#Differences of septic trauma survivors vs septic trauma deaths ($P<.0001$).

present multivariable analysis was undertaken to sort out the relative influence of all these factors (muscle proteolytic catabolism with endogenous AA release, TPN-administered AAs, and hepatic dysfunction related to development of overt or occult organ failure).

AA Uptake as a Determinant of Urea Production

Table 3 shows the mean and SDs of the plasma levels of each AA studied in the three different groups of patients (NST, ST survivors, and ST deaths) in the early and late phase of the posttrauma response. This table shows that as sepsis progresses, both in time as well as in severity (MOFS), the plasma levels of the neutral, sulfur-containing, and aromatic AAs rise significantly, while the branched-chain AA plasma levels either rise slightly or actually fall in the patients with late MOFS compared with other ST patients.

To investigate the importance of AA metabolism as a source of urea N production in trauma and sepsis, the uptake of each of the ten AAs noted in the "Patients and Methods" section was studied. Figure 2 shows the multiple regression of urea N production from the total uptake of the two AAs that are quantitatively most important for liver gluconeogenesis: ALA and glutamine plus glutamate (GLUT). Urea N production is expressed in this figure in millimoles per hour, to allow a quantitative evaluation of the relationship between ureagenesis and uptake of AAs. (It must be remembered that each millimole of urea represents the N from two amino groups.) It is interesting that while the uptakes of GLUT and ALA do not equal the urea N, they can explain almost 66% of the urea N production variability ($r^2=.655$; $P<.0001$), if the effect of sepsis is considered (Fig 2). This suggests that ureagenesis from other AAs bears a fairly constant relationship to that derived from these two AAs. However, the critical aspect of this analysis is that, for any level of ALA uptake and any level of GLUT uptake greater than 0.5 mmol/h, the presence of sepsis is associated with a significant increase in expected production of urea N ($P<.05$ by the Scheffé S method). This is consistent with the increased urea N production rate per gram of estimated proteolysis shown in Fig 1 and suggests a resetting of the oxidative catabolic machinery in sepsis. Alanine and glutamine (via transamination in the gut to ALA)[33,34] are major gluconeogenic precursors, and as a result, the plasma glucose levels are seen to rise in this group of ST patients. This is shown in Fig 3, where the levels of plasma glucose and the estimated extracellular water (ECW) pool of glucose in ST and NST patients are seen to increase as an inverse function of the glucose input rate (ratio of glucose infusion rate to the plasma glucose level, corrected to estimated ECW pool size) and as a direct function of the ALA uptake. At the lower ranges of glucose uptake and at the higher ranges of alanine uptake, the regression predicts that the ST patients have a larger glucose pool than the NST patients. In a patient with an average ECW (17.2 L), 1 mmol/L of glucose represents a bit more than 1 mg/dl of plasma glucose: thus, the ST patients with very large glucose pools are also very hyperglycemic. These data are consistent with observations that demonstrate a higher rate of ALA gluconeogenesis[35] and a reduced level of glucose oxidation in sepsis[36] so that turnover and pool size increase.[11]

These data (Figs 2 and 3) suggest that the diversion of ALA to gluconeogenesis may be a major source of AA N

Fig 2.—Dependence of urea nitrogen production on central uptakes of alanine (ALA) and glutamate plus glutamine (GLUT). **Urea N (millimoles per hour) = 0.61 (ALA millimoles per hour) + 7.76 (GLUT millimoles per hour) + 9.26 (GLUT millimoles per hour) × (Sepsis) − 4.39 (Sepsis) + 2.45.** Statistical significance of covariance effect of sepsis was tested by Scheffé S method and showed significant effect ($P<.0001$) both on intercept and on slope. Septic trauma patient points shown by S. Nonseptic trauma patient points by minus sign.

Fig 3.—Prediction in septic trauma (ST) and nonseptic trauma (NST) patients of variability of estimated glucose pool size (total millimoles of glucose in extracellular water [ECW] volume) by the eight-hour glucose input (GLI [in millimoles]) as percent of total estimated ECW pool of glucose (GLECW = mean eight-hour plasma glucose [in millimoles per liter] × estimated ECW [in liters]) and by central uptake of alanine (ALACU [in millimoles per hour]). **Glucose Pool (mmol) = 57.5 (Sepsis) + 4.686 (ALACU) + 3.217 (ALACU) × (Sepsis) + 9.54 / (GLI/GLECW) + 32.72 / (GLI/GLECW) × (Sepsis) + 75.59.** Scale at right shows estimated level of plasma glucose (milligrams per deciliter) corresponding to each value of estimated glucose pool size (millimoles), using mean estimated ECW volume of all patients (17.2 L). Since inputs were quantified on an eight-hour basis, eight-hour glucose input (GLI) is quantity of glucose infusion during each eight-hour period (millimoles) to maintain observed mean level of plasma glucose. Central uptake of alanine (ALACU) is mean quantity per hour of total parenteral nutrition alanine infusion (millimoles per hour) plus estimated quantity of alanine release (millimoles per hour) per gram of muscle protein degradation to maintain observed plasma level of alanine.[14] Estimated glucose pool size was derived from mean plasma glucose level during GLI period times estimated ECW as previously described.[14] Increase in the magnitude of estimated ECW glucose pool in ST over NST for given GLI and ALACU reflects increase in GLECW due to endogenous gluconeogenesis with additional glucose release into pool above that infused and to sepsis mediated reductions in glucose utilization from pool during GLI period. In sepsis GLI/GLECW ratio falls to greater extent than NST because GLECW is increased.

for potential ureagenesis, and that the effect of the increased glucose synthesis is greatest in the sicker ST patients, since proportionately less glucose is being oxidized, so that plasma glucose levels increase. In the ST patients with MOFS studied, this generally resulted in a clinical reduction in the rate of TPN-infused glucose, to reduce the excessive hyperglycemia shown in Fig 3 and in Table 2.

Muscle Catabolism and AA Infusion as Determinants of Urea Production

Figure 4 shows the multiple regression-covariance analysis of the dependence of urea N production on muscle protein degradation, with its presumed release of AAs, and on AA infusion from TPN. In the total patient population (ST and NST), AA infusion and muscle proteolytic catabolism (estimated from 3MH), which are the sources of exogenous and endogenous AAs, respectively, explain 79% of the variability of urea N production ($r^2=.791$, $P<.0001$). However, by the use of the bar diagram technique, in which the mean value of each variable is multiplied by its regression coefficient, the relative effect of each independent variable (catabolism and AA infusion) can be assessed with regard to its effect on urea N production in NST patients and in ST patients. The Scheffé S method,[32] for the simultaneous contrast of all differences, was used to determine the significant differences between these two groups of patients.

Septic trauma patients (including both early and late courses, survivors, and nonsurvivors) have a higher estimated mean value of urea N production (743 mmol/d) than NST patients (439 mmol/d) due to the effect both of the increased AA infusion rate and of the increased muscle protein degradation (ie, increased total supply of AAs). However, despite the increased TPN-AA infusion rate in sepsis, a significant ($P<.05$ by the Scheffé S method) *difference* between ST and NST patients was found in the increased *relative* effect of muscle catabolism on ureagenesis. Counterbalancing this, there is a significant ($P<.01$) *negative* effect of sepsis on the urea N production intercept value, which accounts for the remaining unexplained variability in urea production. This seems to be associated with the septic insult itself, and will be partially explained when Fig 7 is discussed below.

In summary, in sepsis, the actual value of urea N production is the result of the interaction of the positive effect of TPN-AA infusion and of the increased muscle catabolism, but the significant increment due to sepsis appears to be correlated with the sepsis-enhanced proteolysis. However, there is also a negative *additional* effect due to sepsis. There appears to be no difference in the regressions testing this effect of sepsis if only ST survivors or ST deaths are considered, with the difference in urea N production being explainable by differences in the above independent variables.

Fig 4.—Relative dependence of urea nitrogen (N) production (mean value estimated from regression) on amino acid infusion and muscle catabolism, in septic trauma and nonseptic trauma patients. See "Statistical Methods" section for explanation of bar graph. All regression coefficients were obtained from multiple regression covariance analysis: n = 80; $r^2 = .791$; $F(4,75) = 70.8$; and $P < .0001$. Covariance differences between septic trauma and nonseptic trauma tested by Scheffé S method.

Effect of Differential AA CLRs on Urea Production

To analyze further the additional negative effect of sepsis on urea N production demonstrated in Fig 4, the relative CLRs of each of the AAs studied were compared with the CLR of leucine. This was done because earlier studies[14] suggested that the leucine/tyrosine CLR ratio (L/T ratio) obtained at a constant leucine to tyrosine TPN infusion ratio was a functional index of hepatic impairment in sepsis and ST MOFS. Representative leucine to other AA CLR ratios are shown in Fig 5, with regard to the simultaneous statistical comparisons among NST patients, early ST survivors (less than five days after trauma), late ST survivors (more than five days after trauma), and ST MOFS deaths. A decrease in the slope of the clearance relationship means a rise in the leucine-AA CLR ratio. Except for the aromatic AA, progression of sepsis from early to late caused an increase in the leucine-AA CLR ratio compared with NST patients for all nonbranched AAs studied (of which proline and methionine are shown). However, there was no further leucine-AA CLR ratio increase between late ST survivors and ST MOFS deaths. Only when the aromatic AAs, phenylalanine and especially tyrosine, were considered was there a further increase in the leucine-AA CLR ratio as the MOFS developed. Since in these comparisons, the percent pool appears in both ordinate and abscissa, any error due to pool size estimation cancels out. This is an important observation with relevance to hepatic function in sepsis, since while leucine is cleared by both peripheral tissues and liver, tyrosine is almost entirely metabolized in the liver.[14,37] Thus, the L/T ratio provides a sensitive index that can be used to investigate the role of sepsis-induced hepatic dysfunction in modulating the posttraumatic ureagenic response to muscle proteolysis and TPN-AA infusion.

Figure 6 shows the relationship between urea N production and the L/T CLR ratio. This regression covariance analysis demonstrates a negative correlation between the two measurements, both in ST and NST survivors following trauma, with urea N production falling as the L/T ratio increases. Since the coefficient for sepsis is significantly positive (17.44), this indicates that for the same value of the L/T ratio, ST survivors have a consistantly higher rate of urea N production. The secondary lines show the 95% confidence limits of the regression lines for ST and NST survivors.

Thus, the effect of progressive or sustained sepsis, in the absence of the MOFS with hepatic dysfunction, is to produce an increased efficiency of ureagenesis for each level of hepatic CLR of AAs. This difference between ST and NST is highly significant ($P < .0001$ by the Scheffé S method). However, these data also suggest that at any given level of control (sepsis vs nonsepsis), increasing hepatic dysfunction, as measured by using the L/T ratio,[14] reduces the liver's ability to synthesize urea.

The ST nonsurvivors with clinical MOFS were not included in the regression for ST survivors, but their data are plotted on the graph. At any level of the L/T CLR

Fig 5.—Representative amino acid (AA) clearances (CLRs) as compared with leucine CLR **early** and **late** in nonseptic patients after trauma, in septic trauma (ST) survivors, and in ST multiple-organ failure syndrome (MOFS) deaths. Although total amount of AA varied somewhat during clinical course, all patients were given total parenteral nutrition with **constant** leucine to tyrosine concentration ratio as standard total parenteral nutrition. All slope differences tested by Scheffé S method of simultaneous contrasts. Note that only in leucine CLR to aromatic AA CLR relationships is there significant difference between **late** ST survivors and ST MOFS deaths. All regressions shown in figure are highly significant ($P<.0001$). Covariance differences tested for significance by Scheffé S method, P values as shown. NS indicates not significant.

ratio, their production of urea was abnormally low, both early and late in their clinical course. A second effect in the ST MOFS deaths is that, with time, they also trend to higher L/T CLR ratios and, consequently, lower levels of urea N production (Fig 7). This suggests that in the ST MOFS, the decrease in ureagenesis is due not only to a lower hepatic CLR of AAs from the plasma but also to a direct inhibition of ureagenesis, appearing quite early in the course of ST patients with MOFS, even when the level of hepatic dysfunction appears to be quite minimal on clinical grounds.

The interaction of all these factors (muscle protein degradation with release of AAs, TPN-AA infusion, and the impaired CLR of tyrosine relative to the total-body CLR of leucine [L/T ratio] at a constant TPN infusion ratio) is shown in Fig 7 for ST and NST patients, with regard to whether they were studied *early* or *late* in their clinical course. This diagram is generated from a single significant ($P<.0001$) multiple regression, with a covariance analysis that takes into account both the effect of sepsis and the effect of time (early vs late) on each regression coefficient and on the intercept value for that group. The mean values for each variable are shown in parentheses below each effect. The significance of the differences in the coefficients of the regression (double asterisks) and the significance of the coefficients themselves (single asterisk) were all simultaneously tested by the Scheffé S method.

For each type of study (early or late; ST or NST), the bar diagram, in which the mean values are multiplied by their respective regression coefficients, displays the *relative* effect of each of the components of urea production, as estimated by the global multiple regression. In all patients, ST or NST, early or late in their course, both AA infusion

Fig 6.—Regression between urea nitrogen (N) production and leucine clearance/tyrosine clearance ratio in septic trauma survivors and in nonseptic trauma patients; covariance effect of sepsis significant by Scheffé S method. Secondary lines indicate 95% confidence limits of regression lines. Septic trauma patients with multiple-organ failure syndrome (MOFS) are also plotted, but were excluded in regression analysis. **Urea N g/d = −1.62 (Leucine/Tyrosine) + 17.44 (Sepsis) + 22.01.**

and muscle protein degradation are significant determinants of urea N production.

As already noted in the regression of Fig 4, there is an increased relative effect of muscle catabolism in enhancing urea N production in sepsis. This analysis shows it to be significantly different from that seen in NST patients *only* during the late ST period, even though the mean value of muscle catabolism is increased in early sepsis (111 g/d) to a greater extent than in late sepsis (89.5 g/d).

On the other hand, the introduction of an additional variable, which accounts for the relative efficiency of the peripheral AA CLR to the hepatic AA CLR (the L/T CLR ratio) yields important information concerning possible mechanisms of urea synthetic control in sepsis. This ratio, as might be expected from Fig 6, is *negatively* related to urea N production, suggesting that it reflects an inhibitory effect on urea synthesis.

In addition, Fig 7 makes it clear that the unexplained negative effect of sepsis, shown by the intercept value in the bar diagram of Fig 4, is now largely explained by this new independent variable, the index of hepatic AA CLR (L/T CLR ratio). This strongly suggests that in the ST state, the enhancement of ureagenesis due to the increased hepatic gluconeogenesis and oxidative catabolism of AA, is partly counterbalanced by a relatively impaired efficiency of the liver in clearing plasma AAs for metabolism.

COMMENT

Both trauma and sepsis independently can induce muscle protein degradation, with an increased loss of urinary N associated with an accelerated gluconeogenesis and ureagenesis. The mechanism of this accelerated proteolysis in the skeletal muscle has been extensively studied.[1] While some authors have stressed the role of increased circulating levels of catabolic hormones (catecholamines, corticosteroids, and glucagon)[4] or catabolic mediators,[2] others[5,16,36] have explained proteolysis by a peripheral impairment of glucose oxidation (postreceptor insulin resistance), which would compel the skeletal muscle to use alternative fuels, including the keto acids derived from the branched-chain AAs of its own structural proteins.

The possibility that this may be mediated by a host-defense–related response has been explored by Clowes et al[2] and Loda et al,[29] who have isolated a humoral factor that appears to be the stable circulating cleavage product of interleukin I. This substance can induce both proteolysis in the skeletal muscle and acute (TNF)-phase protein synthesis in the liver. Tumor necrosis factor has also been implicated as a possible causative agent.

The humorally mediated muscle protein degradation (proteolysis) releases AAs in proportion to their molar ratio in actin and myosin. However, in the presence of an impairment of skeletal muscle glucose oxidation, which occurs in sepsis,[6,36] the branched-chain AAs are preferentially oxidized by muscle itself.[33,35] This oxidation, whose first step involves deamination to α-keto acids, is coupled with the synthesis of ALA from muscle pyruvate, which accepts the transaminated amino N.[6,33,34] At the same time, a net synthesis of glutamine also occurs by a similar mechanism of acceptance of amino N by transamination from muscle glutamate. Since skeletal muscle cannot synthesize urea, the synthesis of ALA and glutamine represents the means of disposal of muscle protein–derived AA N. As a result, the final mixture of AAs released from the muscle into the plasma is qualitatively different from the composition of the muscle protein,[33-35] since it is enriched in ALA and glutamine, but it contains less branched-chain AAs. While the plasma ALA is mostly taken up by the liver, a large amount of glutamine is extracted not only by the liver but also by the gut,[33,34] which transaminates it to ALA.

In the normal postabsorptive state, ALA is responsible for only about 10% of glucose production by the liver, but it becomes a more important gluconeogenic precursor in starvation (25%),[33] and other data suggest that it may be even more important after trauma, or during sepsis.[7,9,10,14,16,35] After lactate, ALA appears to be the most important source of carbon for gluconeogenesis; a quantitatively lesser role is played by the other gluconeogenic AAs.[33,34] In particular, the increase in gluconeogenesis during sepsis seems to be accounted for by the utilization of ALA, derived from skeletal muscle protein and lactate.[35] Also, studies with labeled ALA have confirmed the major contribution of ALA to the accelerated gluconeogenesis in ST patients.[35] Furthermore, in sepsis, it appears that gluconeogenesis from ALA cannot be suppressed by exogenous glucose infusion.[11] In experimental sepsis,[10,35] the rate of increase of glucose synthesis appears to correlate only with the availability of sufficient substrate, indicating that the gluconeogenic capacity of the liver is not a limiting factor in ALA uptake. These data are compatible with our observations shown in Fig 3 that the increase in the plasma glucose level at any glucose uptake rate can be correlated with the ALA uptake so as to explain more than 67% of the variability in plasma glucose.

During accelerated gluconeogenesis, the amino group of ALA contributes importantly to the synthesis of urea. Quantitatively, the increased utilization of gluconeogenic AAs as substrate for gluconeogenesis in the liver is sufficiently large that the amino N generated can account for most of the increase in urea formation during trauma and/or sepsis.[35] However, while most of the ALA uptake is accounted for by the liver, the "central" uptake of glutamine is due to an overall *splanchnic* uptake (gut, kidney, and liver). Nevertheless, the weight of glutamine uptake in predicting urea production (Fig 2) is not surprising, since part of the amino N carried by glutamine may finally reach the liver as ALA (synthesized by the gut and kidney) or as serine (synthesized by kidney).

Fig 7.—Relative dependence of urea nitrogen production on amino acid infusion, muscle catabolism, and leucine/tyrosine clearance ratio in septic trauma (ST) and nonseptic trauma (NST) patients, **early** (less than five days) and **late** (more than five days) after injury. See "Statistical Method" section for explanation of bar graph. All regression coefficients obtained from multiple regression covariance analysis on combined groups: n = 80; $r^2 = .821$; $F(4,75) = 86$; and $P < .0001$. Coefficients of regression (single asterisk) and differences in coefficients (double asterisks) are simultaneously significant by Scheffé S method. Regression derived estimated nitrogen (grams per day) **above** compared to actual mean values in parentheses **below** designated by [a]. Mean values for AA infusion and muscle catabolism given in parentheses in grams per day.

Quantitatively, in sepsis, ALA appears to be much more important than glutamine. Indeed, some of our late ST patients had a mean hourly uptake of ALA of over 12 mmol/h, which could theoretically yield 12 mmol/h of urea N or nearly 30% of the mean urea N production. This is, in part, due to the fact that all our patients were supported by TPN, so that they were utilizing both the muscle-released and the TPN-infused ALA, while glutamine was not administered in the TPN. In our data, the combined ALA and GLUT uptake plus the effect of sepsis explain 66% of the variability of urea N production. More important, these data (Fig 2) show that sepsis per se may significantly increase the mean rate of urea N production from ALA.

It must be emphasized that the AAs that are cleared by the liver may also be utilized for protein synthesis. In patients who have undergone trauma, and especially if sepsis occurs, the proportion of AAs utilized for synthesis of enzymes, liver structural proteins, plasma proteins, and acute-phase reactants may be higher than the proportion of AAs whose carbon is used for glucose production or for oxidation to energy. Clowes et al[7] found that in ST patients who were fasting, the release rate of AAs from the muscle was increased three times over normal, while the total-body loss of N was increased by only 30%, suggesting that a large part of these AAs were utilized for protein synthesis. However, our data suggest that competition for AAs between oxidative catabolism and protein synthesis may be responsible for the acute-phase protein reprioritization seen in sepsis.[15] Furthermore, in the prediction of the variability of urea formation, there were two other important factors to be considered, the *sepsis effect* and the *death effect* due to the development of a fatal ST MOFS with hepatic dysfunction.

Effect of Sepsis

As noted above, if compared with NST patients, ureagenesis was enhanced in ST survivors: this increase in

ureagenesis appears to be related to the increase in AA-derived gluconeogenesis, through the increased supply of AAs from the peripheral tissue and from TPN. However, our data show that despite the high rate of TPN given to the ST patients, increased catabolic muscle protein degradation played the major role in causing a higher urea N production (Fig 4).

This dependence of urea production on increased proteolysis seems to be a phenomenon typical of the overt, clinical phase of sepsis, even though the highest mean values for muscle catabolism were reached earlier in the clinical course, during the first few days after the injury. This is clearly shown by the bar diagram in Fig 7. If one compares the relative effect of muscle catabolism on ureagenesis, between the pre-ST period and the overt ST period, it can be seen that the largest significant effect is during the *late* phase of sepsis, despite the fact that muscle catabolism is generally higher during the *early* phase. One explanation may be the increased production of interleukin I, which occurs in sepsis.[2] Its degradation product, proteolysis-inducing factor, has been shown to increase both muscle catabolism and hepatic protein synthesis.[29] This may imply that urea synthesis may be directly or indirectly coupled to the monokine–mediated proteolysis and thus statistically more dependent on muscle catabolism–released AA than on AA administered by TPN, which may not be in phase with interleukin I (or TNF) production.

In addition, there may also be an increased "efficiency" of ureagenesis by direct hormonal stimulation of gluconeogenesis and/or ureagenesis. It is known that high plasma levels of ALA can stimulate glucagon secretion, which is a gluconeogenic hormone.[34] It is also known that usually the coupling of gluconeogenesis and ureagenesis is optimal, despite the fact that these two processes have been shown in vitro to depend on, and compete for, adenosine triphosphate.[38] However, in vivo studies in nonseptic animals show that ureagenesis is generally not decreased, even when the rate of gluconeogenesis is relatively high.[35,38] On the contrary, overstimulation of ureagenesis (in the nonseptic liver) can reduce the gluconeogenic activity, because of competition for adenosine triphosphate or aspartate.[38]

As long as there are adequate oxygen consumption and energy availability and adequate stimulation by an increased supply of gluconeogenic substrates and by a high glucagon-insulin ratio, experimental studies suggest that the normal liver can go on producing glucose and synthesize urea at maximal rates,[10] while, at the same time, synthesizing proteins required for immunologic defense and maintenance of organ function.[8,9] This is what appears to happen in the compensated response to human trauma, in the absence of sepsis and ST MOFS, where acute-phase protein reprioritization occurs.[15]

However, as a limiting factor to sepsis-induced increased ureagenesis, the hepatotoxic effect of sepsis (as measured by the L/T ratio[14]) selectively alters the liver's ability to catabolize AAs, causing a relative negative effect on urea synthesis. The latter factor appears to become more prominent in late sepsis as the MOFS develops fully, but it is significant in all late ST patients, regardless of whether fatal MOFS occurs or not.

Effect of MOFS (Septic Death Effect)

In our study, ST patients with MOFS were strikingly different from ST survivors, since their clinical course showed a progressive decrease of urea excretion and a decrease in muscle catabolism. In the late course of ST patients with MOFS, muscle protein degradation (catabolism) was significantly lower, if compared with ST survivors. However, it was not significantly different from the muscle catabolism value in NST patients. Nevertheless, the ST patients with MOFS had a mean production of urea N that was less than one third of the urea N production in the NST patients.

The reduced muscle catabolism might be explained as an adaptive mechanism due to liver failure and the MOFS, in that the increased circulating plasma levels of AAs, due to the reduced AA CLR by the liver in MOFS, may inhibit further muscle proteolysis. It is also possible that some aspect of ST MOFS may directly inhibit production of the proteolysis-initiating factors, as suggested by G.H.A. Clowes, MD (oral communication, June 1987).

On the liver side of urea metabolism, the decrease in urea synthesis may be due to the reduced muscle protein degradation, reflecting a lower muscle catabolism; to the failure of hepatic uptake of AAs; and to the iatrogenic reduction in the TPN infusion rate, because of the observed insulin-resistant hyperglycemia. However, the main significant effect that is evident in the multiple correlation shown in Fig 7 is that *all* ST patients (including both survivors and patients with MOFS) share an inhibiting effect on urea production due to a relative impairment of all hepatic AA CLRs, except for the branched-chain AAs,[14] as expressed by the L/T CLR ratio. This effect becomes even more important in the setting of MOFS, when the source of circulating AAs due to muscle catabolism (and TPN) is decreased. A similar finding was reported by Loda et al[29] and Pearl et al,[30] who found in both ST patients and cirrhotic patients[39] undergoing surgical procedures that nonsurvivors were characterized by significantly lower central CLRs of AAs if compared with survivors.

The reduced ureagenesis may be also due to a failure of gluconeogenesis. In recent experimental studies,[40] hepatic gluconeogenic capability was found to be depressed in severe, late sepsis. However, since this was evident *before* the final onset of depressed, oxidative capability, the mechanism of this selective failure of gluconeogenesis remains obscure. However, hypoglycemia did not occur in any of our clinical patients with MOFS, but rather hyperglycemia, which suggests a different mechanism than the terminal failure of glucose synthesis seen with endotoxemia.

There may be a relative energy failure, since ureagenesis is a synthetic pathway that requires energy (approximately 147 to 168 kJ are required for the synthesis of 1 mol of urea),[35,38] and gluconeogenesis from AAs (more important quantitatively in ST patients) consumes more energy than gluconeogenesis from lactate or pyruvate.[34] At the same time, the ST liver also appears to be maximally stimulated to the synthesis of a variety of proteins, especially acute-phase reactants, at a rate that might be expected to require large amounts of energy.[15,29] However, oxygen consumption, while reduced in some patients with late MOFS,[16,41] was not significantly lower than that in surviving ST patients in this group.

All studies were carried out in accordance with the guidelines of the Human Investigations Committee of the University of Maryland School of Medicine, Baltimore.

An Ecogenetic Hypothesis for Lung Cancer in Women

Ralph I. Horwitz, MD; Laurie F. Smaldone, MD; Catherine M. Viscoli, MPhil

Epidemiologic studies have established a strong association between cigarette smoking and lung cancer, but the risk estimates for women are less impressive than for men. We assessed the possible role of family history and its interrelationship with cigarette smoking as risk factors for lung cancer in women by conducting a case-control study. Among 112 cases, 7% had a primary family member with lung cancer compared with only 3% of 224 controls for an odds ratio of 2.8. Cigarette smoking was present for 87% of the cases and 41% of the controls for an odds ratio of 11.3. The ecogenetic interrelationship of cigarette smoking and family history was supported by the gradient in the odds ratio for lung cancer created by the two variables: patients who never smoked but had a positive family history had an odds ratio of 5.7; patients who smoked but had a negative family history had an odds ratio of 15.1; and patients who smoked and had a positive family history had an odds ratio of almost 30. We conclude that family history may be an important risk factor for lung cancer in women, and that the ecogenetic interrelationship of family history with cigarette smoking may help explain the occurrence of this disease in women (*Arch Intern Med* 1988;148:2609-2612).

Isolated Regional Perfusion in the Treatment of Subungual Melanoma

Peter C. Baas, MD; Harald J. Hoekstra, MD, PhD; Heimen Schraffordt Koops, MD, PhD; J. Wolter Oosterhuis, MD, PhD; Jan Oldhoff, MD, PhD

• Subungual melanoma is rare and represents only 1% to 3% of all diagnosed melanomas in Western countries. The tumor is frequently mistaken for a benign lesion and the delay in diagnosis and final treatment may be responsible for the high local recurrence rate and the low disease-free survival rate. From 1965 to 1982 the combined-modality therapy of amputation and adjuvant isolated regional perfusion with melphalan with or without dactinomycin was used in the treatment of 22 patients with subungual melanoma. Disease was staged according to the M. D. Anderson classification, as follows: stage I (primary melanoma), 11 patients; stage IIIA (in-transit metastases and/or satellitosis), three patients; stage IIIB (regional lymph nodes), seven patients; and stage IIIAB (in-transit metastases and/or satellitosis and regional lymph nodes), one patient. There were no cardiovascular complications and no treatment mortality. During a follow-up of at least 4.5 years, 12 patients (55%) developed distant metastases, including four patients with stage I disease (36%) and eight patients with stage III disease (73%). There were no locoregional recurrences. The median survival was three years (range, 0.5 to 12.5 years) and the overall five-year survival was 40%, with 56% of patients having stage I disease and 27% having stage III disease. The prognosis of subungual melanoma is determined by the stage of the disease. Isolated regional perfusion may prolong disease-free survival in patients with subungual melanoma compared with previously published data.

(*Arch Surg* 1989;124:373-376)

In 1834, Boyer[1] described a 57-year-old man with a subungual melanotic neoplasm located at the tip of the left little finger and an enlarged lymph node in the axilla. A subungual "black line" under the nail remained stationary for 28 years but started to grow slowly and caused pain. In the course of the next two years the pigmented area widened, became inflamed and painful, and bled on the slightest touch. Finally, an amputation through the middle phalanx was performed for a tumor the size of a chicken egg located at the fingertip. The axillary lymph node remained untouched and subsequently disappeared; during follow-up there was no recurrence. In 1855 Demargnay and Monod[2] described a 69-year-old woman with an easily bleeding black tumor on the left thumb that originated from the nail bed and lifted the nail. Shortly after cauterization of the tumor a local recurrence developed with enlarged axillary lymph nodes and an amputation of the thumb was performed.[2] It was Hutchinson[3] who published the first important clinical description of a subungual melanoma in 1857 in an article entitled "Melanotic Disease of the Great Toe, Following a Whitlow of the Nail." In a classic report called "Melanosis Often Not Black: Melanotic Whitlow,"[4] Hutchinson stated that melanoma may occur subungually, that it is a malignant neoplasm, and therefore the primary treatment should be amputation of the involved finger or toe.[4]

Since these early reports, more than a century has passed and only a few case reports and clinical series have been published. Although the incidence of melanoma is increasing and is approximately four per 100 000, subungual melanoma is very rare and represents only approximately 1% to 3% of all diagnosed melanoma in Western countries. A higher proportion of subungual melanoma is diagnosed in dark-skinned patients.[5,6] Subungual melanoma is still frequently mistaken for benign conditions such as subungual hematoma, chronic paronychia, onchymycosis, glomus tumor, and pyogenic granuloma.[7] Amelanotic subungual melanoma exists, but is rarely diagnosed.[8] The delay in diagnosis is believed to be responsible for the low five-year survival rate associated with subungual melanoma in comparison with the survival rate from melanoma at other locations. Improvement in survival can be achieved by early recognition and proper surgical treatment.

Subungual melanomas are close to the underlying periosteum and therefore exarticulation of at least the involved phalanx is the treatment of choice. Axillary or inguinal lymph node dissection is mandatory when the lymph nodes are involved, while some surgeons perform elective node dissections.

From 1965 to 1982 we treated 22 patients with a combination of amputation and adjuvant isolated regional perfusion for subungual melanoma. In all patients with a subungual melanoma of the upper extremity an elective or therapeutic axillary dissection was performed to enable better perfusion. In the lower extremity only therapeutic lymph node dissections were performed. To gain some insight into the results of our treatment, the patients with subungual melanoma treated in this way were evaluated and the existing literature was reviewed.

PATIENTS AND METHODS

Thirty-one patients with a primary subungual melanoma of the finger or toe in the period 1965 through 1982 were evaluated for this combined-modality therapy of surgery and adjuvant isolated regional perfusion at the Division of Surgical Oncology, Groningen (the Netherlands) University Hospital. Of these 31 patients, eight were excluded from perfusion treatment because of distant metastases or unstable heart disease. One patient refused perfusion treatment. Twenty-two patients were treated by isolated regional perfusion with melphalan, with or without dactinomycin, and amputation of the involved finger or toe at the metacarpophalangeal joint or metatarsophalangeal joint. There were 13 female and nine male patients with a mean age of 57 years (median age, 62 years; range, 21 to 81 years). As Table 1 illustrates, the fingers were involved more often than the toes. Five melanomas appeared at the fingers, ten appeared at the thumb, six appeared at the great toe, and one appeared at the second toe.

All patients with a subungual melanoma of the upper extremity

*M. D. Anderson staging system: stage IA, primary melanoma; stage IIIA, satellitosis and/or in-transit metastases; stage IIIB, regional node metastases; and stage IIIAB, satellitosis and/or in-transit metastases and regional node metastases.

†1 indicates amputation; 2, axillary perfusion; 3, iliac perfusion; 4, femoral perfusion; and 5, popliteal perfusion.

‡DOD indicates dead of disease; NED, no evidence of disease; DHI, dead of heart infarct; and DCC, dead of colon carcinoma.

were treated with axillary lymph node dissection for technical reasons, followed by an isolated regional axillary perfusion and amputation of the thumb or finger. Patients with lower extremity subungual melanoma were treated with isolated regional iliac perfusion and amputation of the toe, followed six weeks later by a second popliteal perfusion. In two patients with suspect inguinal lymph nodes, an inguinal lymph node dissection with femoral perfusion was performed instead of popliteal perfusion.

The histologic specimens were reexamined by one of us (J.W.O.) and microstaged according to Clark et al[9] and Breslow.[10] Sixteen patients' lesions were staged as Clark IV and five as Clark V; one patient's lesion could not be staged according to Clark's classification. The median Breslow thickness was 5 mm (range, 1.4 to 15 mm). The disease was classified according to the M. D. Anderson classification, as follows: stage IA (primary tumor), 11 patients; stage IIIA (satellitosis and/or in-transit metastasis), three patients; stage IIIB (regional node metastases), seven patients; and stage IIIAB (satellitosis and/or in-transit metastasis with regional lymph node metastasis), one patient. The follow-up was at least 4.5 years for the living patients. Clinical data, microstaging, tumor stage according to the M. D. Anderson classification, treatment, and follow-up are summarized in Table 1. When a median number is mentioned, this number is determined from real data. For the statistical analysis we used the Kaplan-Meier method.

Hypothermic or normothermic isolated regional perfusions were performed from 1965 to 1969, while all perfusions performed since then have been under hyperthermic conditions.

For perfusions of the lower extremity a lower abdominal incision paralleling the inguinal ligament or through a paramedian incision was used. The vessels were approached through the retroperitoneal space. An iliac lymph node dissection was always performed for technical reasons. The inferior epigastric and obturator vessels were ligated. After general heparinization (heparin sodium, 3.3 mg/kg of body weight) the internal iliac artery was temporarily occluded. The external iliac artery and vein were cannulated. The collateral circulation was blocked by means of a tourniquet placed around the thigh as high as possible to prevent leakage of cytostatics to the systemic circulation. For perfusion of the upper extremity an axillary lymph node dissection was performed for technical reasons, the axillary artery and vein were exposed and cannulated, and the collateral circulation was blocked using a tourniquet around the arm.[11] The extremity was perfused with the aid of a pump oxygenator; the perfusate (350 mL of dextran, 500 mL of blood, and 30 mL of 8.4% sodium bicarbonate and heparin sodium) was heated for the hyperthermic perfusions with a heat exchanger in the oxygenator. Adequate tissue oxygenation could be obtained and maintained only when the perfusion pressure was no lower than 15 mm Hg below the systemic mean arterial pressure.[12] The extremity temperature was monitored by four thermistor probes inserted through the skin into the subcutaneous tissue and the muscles of the upper and lower ends of the upper and lower extremities. Administration of the drug(s) was started when the subcutaneous tissue temperature of the lower part of the extremity reached 38°C. Leakage from or to the systemic circulation was checked with the aid of a scanner placed over the heart using radioactive iodine (^{131}I) bound to human albumin as an isotope. The duration of the perfusion was 60 minutes. After its completion the extremity was washed out with an inert fluid, whereupon the catheters were removed, the vessels were closed, and the heparin was antagonized with protamine chloride. After completion of the perfusion the thumb, finger, or toe was amputated at the metacarpophalangeal or metatarsophalangeal joint. A fasciotomy was performed to prevent a compartment syndrome.[13] For femoral perfusions, first a superficial inguinal lymph node dissection was performed, followed by cannulation of the femoral vessels immediately below Poupart's ligament. When popliteal perfusion was performed, the cannulae were introduced at the level of the adductor canal. The technique for femoral and popliteal perfusion was the same as described above.

Melphalan (L-phenylalanine mustard) was used in dosages of 1 to 1.5 mg/kg of body weight for the lower extremity and 0.5 to 0.7 mg/kg of body weight for the upper extremity. Since 1982, the

melphalan dosage has been calculated on the basis of the extremity volume.[14] Melphalan was given at a dosage of 10 mg/L of perfused tissue. For patients with stage I lesions, melphalan alone was used as the cytostatic drug for perfusion. For satellitosis or in-transit metastases at stage IIIA or IIIAB, 0.5 to 1 mg of dactinomycin was added to the perfusion fluid (maximum, 0.006 and 0.014 mg/kg of body weight for the upper and lower extremity, respectively). Anticoagulation was started the day after perfusion and continued until full mobilization was achieved. Antimicrobial agents were not routinely given either preoperatively or postoperatively.

RESULTS

There were no complications during the perfusion treatment or during the 30-day postoperative period. No patient died as a result of this therapy. The median survival was three years (range, 0.5 to 12.5 years); the overall five-year survival according to the Kaplan-Meier test was 40%; for stage I disease it was 56% and for stage III disease it was 27% ($P<.05$) (Fig 1). During a follow-up of at least 4.5 years, 12 patients (55%) developed distant metastases, including four patients (36%) with stage I disease and eight patients (73%) with stage III disease, after a median time of 13 months (range, three to 33 months). There were no locoregional recurrences in the extremities (Fig 2).

Tissue reaction by the extremity was seen approximately two days after hyperthermic perfusion. The perfused extremity was red, warm, and slightly edematous. Cardiovascular complications during the surgical perfusion procedure or in the postoperative period were not observed, and no patient died as a result of this therapy. Two patients (9%) developed complications. During follow-up one patient

developed dystrophy of the forearm with edema of the proximal arm and another patient developed contractures of the little and ring fingers after amputation of the middle finger.

COMMENT

Subungual melanoma is very rare in Western countries, in contrast with Japan, where it represents 19% of all diagnosed melanomas.[5,6,15] It is a slow-growing tumor. There are only a few well-documented series of patients with subungual melanoma published in the literature, as summarized in Table 2.[5,6,15-19] The tumor is most often diagnosed in the sixth decade.

The fingers are more often involved than the toes. In nearly three fourths of all patients it was either the thumb or the great toe that was affected. The relatively frequent occurrence of subungual melanoma in the thumb and the great toe is unexplained and intriguing. Extreme exposure to ultraviolet (UV) light may be one of the exogenous causes of subungual melanoma. Fingers suffer more exposure to UV light than do the shoe-covered toes. Subungual melanoma of the toes was more frequently diagnosed in women,[5] who wear open-toed shoes more often, than in men,[1] supporting the UV light hypothesis.

The clinical diagnosis of a subungual melanoma is often missed by the primary physician because of the benign clinical aspect or a history of a trauma that causes a treatment delay. Most likely because of the delay, 50% of the patients already had local or regional metastases. There is no causal relationship between trauma or chronic infection and subungual melanoma, although trauma has been mentioned in 34% of cases of subungual melanoma.[15,17,18]

The prognosis of a melanoma depends on the histopathologic features of the primary, based on the depth of invasion and thickness of the tumor, and the presence of local, regional, or distant metastasis at the time of diagnosis. It is very difficult for a pathologist to describe the depth of invasion and the tumor thickness of a subungual melanoma based on a small biopsy specimen. Adequate histologic staging requires a partial amputation to provide an adequate biopsy specimen. Nail destruction and invasion of bone are specific prognostic factors for a subungual melanoma.[19] All subungual melanomas in this series were high-risk tumors at Clark stages IV and V and with a Breslow thickness greater than 1.5 mm.

When a subungual melanoma finally is diagnosed, how should this unusual tumor be treated? How wide should local excision of the tumor be? In their first article Pack and Adair[7] advocated amputation in the metacarpophalangeal or metatarsophalangeal joint. Later Pack and Oropeza,[6] as well as Papachristou and Fortner,[19] asserted that any amputation below the carpometacarpal or tarsometatarsal level was inadequate as far as local recurrence is concerned. We administered isolated regional perfusion followed by amputation at the metacarpophalangeal joint or metatarsophalangeal joint and no local recurrences were diagnosed. Patients with clinically palpable nodes should undergo lymph node dissection. The question of whether an elective or prophylactic regional lymph node dissection is of any value is still controversial.[19]

In the majority of the published series only the five-year survival rate, but not the rate of locoregional control, is mentioned (Table 3). It seems that in our series hyperthermic isolated regional perfusion did not improve the survival of the patients with a subungual melanoma, but 100% locoregional control was achieved without severe morbidity and no mortality.

Isolated hyperthermic regional perfusion in the treatment of melanomas of the extremities is still controversial. At this writing, a prospective randomized trial to investigate the value of hyperthermic isolated regional perfusion in the treatment of a primary extremity melanoma with a thickness of 1.5 mm or more was under way in Europe. As has been suggested by Franklin et al,[20] those patients with a subungual melanoma without distant metastases might benefit from perfusion therapy, just like those patients with local recurrence, satellitosis, or in-transit metastases from a nonsubungual extremity melanoma without distant metastases.

We thank Leo T. van der Weele for the statistical analysis of the data.

Editorial Comment

Although this is a rare melanoma, the authors emphasize that the diagnosis is made late because this tumor is confused with benign conditions. Since the survival rate is determined by the stage of the disease, a high index of suspicion is essential to detect lesions in early stages. Treatment with amputation and adjuvant isolated regional perfusion did not improve survival, but substantial palliation was achieved with no instances of local or regional recurrence. Since this is a rare tumor, a randomized control trial would take too long to conduct. With the authors' report of excellent locoregional control, further studies with this treatment regimen are indicated.

Influence of Estrogen Receptors on Survival and Recurrence in Patients With Breast Cancer Without Lymph Node Metastases

Hope S. Maki, MD, James L. Hoehn, MD

• A retrospective chart review was conducted to determine the prognostic effect of estrogen receptor (ER) protein in patients with node-negative operable breast cancer. One hundred nine patients with breast cancer whose tumors underwent ER analysis and whose lymph node negativity was established histologically were studied. Based on life-table analysis, the overall survival at six years was 92.7% for ER-positive patients, 95.3% for ER-negative patients, and 94.4% for ER-borderline patients. The disease-free survival was 83.3%, 92.8%, and 71.4%, respectively. Survival and disease-free survival were also correlated to menopausal status. The difference in survival was not statistically significant at six years. We conclude that in node-negative primary operable breast cancer, ER status should not be used as a discriminant for adjuvant treatment.

(*Arch Surg* 1989;124:377-380)

Since the early 1970s, estrogen receptor (ER) determinations on breast cancer specimens have become standard practice. Initially, ER positivity was equated with a more favorable prognosis.[1-11] Recently, other reports have indicated that ER status may have prognostic significance only in a select patient population.[12-15]

The present study was undertaken to review our experience with patients with node-negative breast cancer during a five-year period. In particular, overall survival and disease-free survival (DFS) were examined and correlated with ER status.

PATIENTS AND METHODS

From January 1975 through December 1979, 424 patients were treated surgically for primary breast cancer. From this group, 109 tumors were identified that had no axillary node involvement confirmed on histologic examination and that had undergone ER determinations. Inoperability, metastatic disease, and bilaterality were grounds for elimination from the study. All patients underwent either a radical (11 patients) or modified radical (98 patients) mastectomy.

Estrogen receptor protein analysis was done using a modification of the dextran-coated charcoal procedure described by Liskowski and Rose[16] and previously reported from our institution.[17] The samples were immediately taken to the pathology laboratory, where a portion was sectioned for histologic examination and a portion was quick frozen in liquid nitrogen and stored at −70°C until it was assayed. All ER assays were performed within one week of specimen collection. Specific ER sites are expressed as femtomoles of receptor per milligram of protein. Results were expressed as positive (>10 fmol/mg of protein), negative (<3 fmol/mg of protein), or borderline (3 to 10 fmol/mg of protein). Overall survival and DFS were measured from the date of the pathologically confirmed diagnosis.

Statistical analysis was done according to Kaplan-Meier life-table methods. For comparisons of survival rates where survival was 100% in one of the groups, the confidence limits for the group with less than 100% survival were compared with exact confidence limits from the binomial with zero failures in n trials, where n is the number of patients who were followed up for at least six years. In addition, Cox proportional-hazards regression analysis was used to study the effects of other variables on survival.

RESULTS

Of the 109 patients included in the study, only one was male. The median age was 62 years (range, 28 to 88 years). Twenty-one patients were premenopausal and 87 patients were postmenopausal. The average size of the 104 tumors that were measured was 2.3 cm (range, 0.5 to 7.0 cm). Fifty-two tumors were 2.0 cm in diameter or less, 51 were more than 2 cm and less than or equal to 5.0 cm in diameter, and one tumor was more than 5.0 cm in diameter. Estrogen receptor protein analysis showed 46 patients to be positive, 43 to be negative, and 20 to be borderline. Thirty-three patients had received adjuvant therapy (29 of them with adjuvant postoperative radiation therapy) primarily for medial or central lesions and four patients had received chemotherapy based on a protocol study being conducted at the time. Seventy-six patients were treated with surgery alone.

The mean follow-up time for the entire group was 77.0

*No coefficient was statistically significant.

months. All patients were available for follow-up. The mean DFS was 72.3 months. At the time of chart review, nine patients were alive with disease, nine had died of disease, and 15 had died of other causes. The remaining 76 patients had no evidence of disease.

The mean DFS was 67.2 months for the ER-positive patients, 77.4 months for the ER-negative patients, and 73.1 months for the ER-borderline patients. For patients receiving no adjuvant therapy, the mean DFS was 72.3 months, for those undergoing radiation therapy it was 69.7 months, and for the four patients receiving chemotherapy it was 91.8 months. Table 1 lists the overall survival and recurrence for all patients according to menopausal status at the time of chart review.

Survival and DFS were correlated to ER status using life-table analysis. Figure 1 depicts the overall survival according to ER status. At six years, survival was 92.7% for the ER-positive patients, 95.3% for the ER-negative patients, and 94.4% for the ER-borderline group. Figures 2 and 3 show the overall survival according to menopausal status. The number of premenopausal patients is small (four ER-positive, 13 ER-negative, and four ER-borderline). Respective overall survivals were 100%, 84%, and 100% at six years. Respective survivals among the postmenopausal patients were 92% for the ER-positive, 100% for the ER-negative, and 92.3% for the ER-borderline groups at six years. The differences in survival are not statistically significant.

The DFS for the entire group is shown in Fig 4. At six years 83.3% of the ER-positive, 92.8% of ER-negative, and 71.4% of ER-borderline patients were free of disease. The DFS probability for the ER-negative group was greater than for the ER-positive and ER-borderline groups at six years. The difference between the ER-negative and ER-borderline group was of borderline significance ($Z = 1.84$). The DFS according to menopausal status was examined. Among the premenopausal patients, DFS was 100%, 76.2%, and 75%, respectively, at six years for the ER-positive, ER-negative, and borderline groups. The differences were not significant because of the small numbers in the subgroups (Fig 5). Among the postmenopausal patients, the DFS was 81.6%, 100%, and 68.1% for ER-positive, ER-negative, and borderline groups, respectively, during the same time period (Fig 6). The DFS probability for ER-negative postmenopausal patients was greater than for ER-positive or ER-borderline patients at six years, but the difference was not statistically significant.

Because the patients with breast cancer were of a variety of ages and had differences in tumor size and menopausal status, Cox proportional-hazards regression analyses were performed to see whether adjustment for these factors would influence the survival patterns with regard to the ER level. The best-fitting models as determined by the likelihood ratio test were those using the continuous measurement of the ER level, rather than classification as positive, negative, or borderline. Table 2 shows the estimated regression coefficients for overall survival and disease recurrence. In both cases the coefficient for the ER level is very close to zero and is not statistically significant. When patients were classified as ER-positive, ER-negative, or ER-borderline, the coefficient for the ER-negative group was negative and approached statistical significance in all analyses, suggesting that these patients as a group had a more favorable prognosis compared with the ER-borderline and ER-positive patients. These analyses support the life-table results.

Additional regression analyses were done using only postmenopausal patients, with no change in the results. In an attempt to control for the effect of differences in treatment, an additional set of analyses was done using only those patients who had undergone a modified radical mastectomy and who did not receive initial adjuvant treatment. Again, the results were unaffected.

It is important to recognize that the analyses in the present report are based on a relatively small sample of patients. Nevertheless, there was no evidence from any of the analyses that positive ER status was associated with improved survival. In fact, there was evidence that ER-negative patients enjoyed a more favorable prognosis.

COMMENT

When the ER protein assay gained widespread use in the early 1970s, it was noted that ER-positive patients with metastatic breast cancer as a group had a more favorable response to endocrine therapy than those patients with ER-negative determinations.[1] Shortly thereafter, Walt and coworkers[2] reported that ER positivity was also associated with an improved survival. Knight et al[3] noted a statistically significant increase in early recurrence in ER-negative patients that was independent of age, tumor size, location, or axillary lymph node status. Allegra and coworkers[4] in 1979 reported similar results that also were independent of age, menopausal status, tumor size, and nodal status. Furmanski et al[5] confirmed their earlier finding that patients with ER-positive tumors survived longer and had a longer DFS.[6] Numerous other reports of similar findings have been published.[7-11]

Several studies have recently proposed that this association between ER status and prognosis does not pertain to all subgroups of patients. In 1980, Hilf et al[12] studied

ER status as a prognostic factor for recurrence as well as response to chemotherapy. The likelihood of recurrence was based on nodal and menopausal status, not ER level. A Norwegian study conducted by Aamdal et al[13] showed that ER status influenced survival and DFS only in patients with positive lymph nodes. Furthermore, during the study period this influence only persisted in the premenopausal women with axillary metastases. A point should be made, however, that in 58 patients (25%) lymph node status was based only on findings from the clinical examination. Axillary dissections were not performed because these patients were older. In 1982 Shapiro et al[14] found that the presence or absence of axillary lymph node metastases, and not ER status, was the most important prognostic variable for patients with breast cancer. Finally, in 1985 Butler et al[15] looked specifically at the same question that the present report examines: Does ER status have prognostic significance in overall survival or DFS in node-negative disease? Five hundred fifty-six patients were followed up for a median period of 75 months. The overall survival and DFS in the entire group and in premenopausal and postmenopausal patients did not change significantly according to ER status. Butler and colleagues[15] concluded that adjuvant chemotherapy should not be considered for patients with ER-negative tumors and histologically negative lymph nodes.

Major advances in the study of the prognosis of breast cancer based on ER protein determinations have been made in the past decade. The hope has been that subgroups of patients will be identified who would benefit from adjuvant treatment following initial surgical intervention. In patients with histologically negative lymph nodes, we failed to demonstrate an effect of ER status on outcome, including either DFS or overall survival. Our results are based on a lengthy follow-up in a stable patient population. However, the study did include a small number of premenopausal patients who may benefit from further study.

Pat Pierce, Steven Broste, MS, and Brian Weiler provided assistance with statistical analysis and Shirley Thompson provided assistance with the figures.

Editorial Comment

Patients with breast cancer who have negative lymph nodes have a relatively favorable prognosis, but some will not be cured by local therapy. A growing number of oncologists consider tumor ER negativity sufficient reason for recommending systemic adjuvant chemotherapy for these patients and this is supported by a recent clinical trial. Maki and Hoehn have found that ERs have no prognostic value and highlight the controversy that continues to exist on this issue. One cannot help but speculate that differing case selection, laboratory methods, numbers of cases, and duration of follow-up, as well as the influence of potent covariables, are contributing to this controversy. To complicate the matter further, the prognosis of node-negative patients varies considerably between institutions and is remarkably good at some, possibly because of earlier diagnosis and more complete staging. The five-year DFSs in excess of 90% regardless of ER status reported by Maki and Hoehn make it plain that the population at high risk for failure may be very small and a challenge to identify. Estrogen receptor status is only one of several prognostic factors in node-negative patients and is likely not the most reliable; it may be a better marker of how to treat than of whom to treat. Nuclear grade, histologic differentiation, intramammary lymphatic permeation, and skin involvement are others. The most promising factors, however, are objective measures of aggressive tumor growth, ie, thymidine labeling index and flow cytometric measurements of S-phase fraction and DNA ploidy. Future decisions for adjuvant therapy will likely be made on these bases.

A Foregut Carcinoid Tumor Causing Zollinger-Ellison Syndrome

Gordon B. Werbel, MD; Suzanne P. Nelson, MD; Philip G. Robinson, MD; John Anastasi, MD; Raymond J. Joehl, MD; Robert V. Rege, MD

• A patient had severe peptic ulcer disease complicated by gastric outlet obstruction and choledochoduodenal fistula. Serum gastrin levels were elevated preoperatively to 340 ng/L. A 1.5-cm histologically benign carcinoid tumor of the antrum of the stomach was found at surgery, and surgical resection of the tumor resulted in normalization of serum gastrin levels and amelioration of the peptic acid diathesis. The patient remains asymptomatic at one year. Immunohistochemical staining demonstrated that the carcinoid indeed contained gastrin along with chromogranin, cholecystokinin, and neuron-specific enolase. This is a case of Zollinger-Ellison syndrome caused by a benign foregut carcinoid (gastric carcinoid-gastrinoma).

(*Arch Surg* 1989;124:381-384)

Carcinoid tumors are most commonly found in the appendix, small intestine, and colon, but they may arise in the stomach, pancreaticoduodenal region, gallbladder and bile ducts, ovary, and pulmonary bronchial tree.[1] These neoplasms arise from enterochromaffin or enterochromaffinlike cells and have the potential to secrete vasoactive substances and hormones. The clinical, histochemical, and biochemical behavior of these tumors varies widely, and their behavior frequently depends on their site of origin.

Kulchitsky's cell tumor or carcinoid tumor of the stomach is a rare gastric tumor. It was originally described by Askanazy[2] in 1923 and accounts for less than 3% of gastrointestinal carcinoids and only 0.3% of all gastric tumors.[1,3,4] Although these tumors histologically resemble other gastrointestinal carcinoids, they are microscopically and clinically most similar to carcinoids of the lung, another foregut derivative. In general, they do not produce the carcinoid syndrome but, if they do, it is an atypical syndrome caused by the secretion of 5-hydroxytryptophan and histamine.[5] Most often, gastric carcinoids are clinically silent or are associated with atrophic gastritis and pernicious anemia,[6-8] while others have been reported to produce acid hypersecretion[8-10] and a syndrome indistinguishable from that described by Zollinger and Ellison.[11]

The following case report illustrates the effects of a gastrin-secreting carcinoid tumor of the gastric antrum. This tumor was associated with severe peptic ulcer disease complicated by gastric outlet obstruction and choledochoduodenal fistula.

REPORT OF A CASE

A 72-year-old man presented to the Veterans Administration Lakeside Medical Center, Chicago, with a three-week history of postprandial nausea and vomiting, anorexia, and weight loss. Peptic ulcer disease had been documented on several occasions over the previous eight-year period by upper gastrointestinal endoscopy and contrast roentgenograms. Fifteen months prior to hospital admission, the patient was hospitalized for gastric outlet obstruction and responded rapidly to administration of an H_2 receptor antagonist, which he took thereafter intermittently for symptoms of dyspepsia and abdominal pain. Other medications included aspirin and sulindac, which were administered for symptomatic rheumatoid arthritis. He also had a 45-pack-year history of cigarette smoking, but he had quit smoking 15 years ago. He denied alcohol ingestion, abdominal pain, flushing, or diarrhea. A fasting serum gastrin level, performed six years prior to hospital admission when he was asymptomatic, was elevated at 200 ng/L (limits of normal [fasting], 50 to 155 ng/L).

On physical examination, the patient was cachectic and profoundly dehydrated. In the supine position, blood pressure was 100/60 mm Hg and heart rate was 100 beats per minute, and, in the sitting position, 70 mm Hg systolic (palpable) and 120 beats per minute; temperature was 36.3°C. Findings from head, neck, chest, and cardiac examinations were unremarkable; the sclera were nonicteric. The abdomen was scaphoid, nontender, and without masses or hepatosplenomegaly. Bowel sounds were active. Rectal examination demonstrated occult blood in the stool.

Several diagnostic tests were performed. Results of a complete blood cell count were normal. Serum electrolytes demonstrated a severe hypokalemic, hypochloremic metabolic alkalosis (potassium, 2.7 mmol/L; chloride, 65 mmol/L; bicarbonate ion, 56 mmol/L); arterial blood gas determinations showed a metabolic alkalosis with partial respiratory compensation (pH, 7.55; carbon dioxide pressure, 54 mm Hg; oxygen pressure, 51 mm Hg; base excess, 29 mmol/L). Ketones were in the urine. Chest and abdominal roentgenograms were remarkable for a markedly distended

Fig 1.—Upper gastrointestinal series in our patient demonstrates two abnormalities: markedly deformed duodenal bulb with partial gastric outlet obstruction (small arrow) and presence of barium sulfate in biliary tree (large arrow).

Fig 2.—Magnification view of duodenum demonstrates duodenal ulcer (small arrow) and choledochoduodenal fistula (large arrow). Barium sulfate flowed freely from duodenum into common duct. Upper endoscopy confirmed presence of active peptic ulcer disease.

stomach, and air was in the biliary tract. An upper gastrointestinal tract series demonstrated a pyloric channel ulcer with gastric outlet obstruction and narrowing of the first portion of the duodenum; a choledochoduodenal fistula was confirmed by free flow of barium sulfate from the duodenum into the common bile duct (Figs 1 and 2). Upper endoscopy showed a benign prepyloric ulcer with surrounding edema; the endoscope could not be advanced into the duodenum.

Fluid and electrolyte abnormalities were corrected by intravenous administration of 2.6 L of balanced salt solutions containing supplemental potassium chloride. A nasogastric tube was inserted to decompress the stomach, and intravenous hyperalimentation was administered. The peptic ulcer was treated with 1600 mg/d of cimetidine hydrochloride by continuous intravenous infusion. The nasogastric tube drained 3 to 4 L/d from the stomach during ten days of treatment. A fasting serum gastrin level, which was drawn after stabilization of the patient's condition with decompression of the stomach by nasogastric suction, was elevated to 340 ng/L. Although Zollinger-Ellison syndrome was considered, performance of a secretin stimulation test was contraindicated by the patient's condition. Furthermore, he was not a candidate for a total gastrectomy. The patient was taken to surgery for exploratory laparotomy and treatment of his gastric outlet obstruction and biliary fistula.

At operation, a benign stricture of the pyloric channel was found. No duodenal, pancreatic, or omental masses were found. A 1.5-cm submucosal mass was palpated in the gastric antrum along the lesser curvature, 1 cm proximal to the pylorus. No hepatic or intra-abdominal metastases were found. A vagotomy and antrectomy, which included the antral mass and adequate margins of resection, were performed. Gastrointestinal continuity was restored with a gastrojejunostomy (Billroth II anastomosis), and the choledochoduodenal fistula was not disturbed. The patient's postoperative course was uncomplicated, and he ate a general diet on his sixth postoperative day. Repeated serum gastrin level was 40 ng/L four weeks after the operation.

On gross examination the antral mucosa demonstrated a 1.5-cm intramural, submucosal, yellow-brown lesion; the lesion had a well-defined border but was not encapsulated. Microscopically, the tumor cells were small and regular; also, the tumor cells had a moderate amount of acidophilic cytoplasm and round regular nuclei with a stippled chromatin pattern (Fig 3). No evidence of tissue infiltration existed. The lymph nodes had no evidence of metastases. There was no evidence of G-cell hyperplasia in the remainder of the gastric antrum. A Grimelius stain showed argyrophilic granules while a Fontana-Masson stain was negative for argentaffinity, indicating that this was a tumor of foregut origin (Table). Thus, the histologic appearance was consistent with a benign carcinoid tumor of the stomach.

Immunohistochemical stains were performed on the formaldehyde-fixed, paraffin-embedded tumor using the peroxidase method of Sternberger[12] as modified by Taylor.[13] Special stains for gastrin as well as chromogranin, cholecystokinin, and neuron-specific enolase were positive. Stains for glucagon, insulin, S100 protein, keratin, somatostatin, serotonin, human pancreatic polypeptide, and corticotropin (ACTH) were negative. The case was

Fig 3.—Left, Pale-staining duodenal Brunner's glands in upper left corner. Note small, regular cells with acidophilic cytoplasm and round, regular nuclei and stippled chromatin (hematoxylin-eosin, original magnification ×40). Right, Higher magnification shows thick cords of neoplastic cells with thin intertwining blood vessels, consistent with benign carcinoid tumor (hematoxylin-eosin, original magnification ×250).

Types of Intracellular Granules in Carcinoid Tumors of the Gastrointestinal Tract*

Derivation of Carcinoid	Argyrophilic Granules	Argentaffinic Granules
Foregut	Present	Absent
Midgut	Present	Present
Hindgut	Absent	Absent

*The types of intracellular granules found in carcinoid tumors are derived embryologically from the foregut, midgut, or hindgut. Note that the carcinoid tumor reported herein stained for argyrophilic but not argentaffinic granules. Thus, it is a typical gastric carcinoid of foregut origin.

reviewed by the Armed Forces Institute of Pathology (Washington, DC), Gastrointestinal Branch, and they agreed with the diagnosis and the immunochemistry findings.

COMMENT

A variety of names have been used to describe carcinoid tumors that secrete gastrin, including carcinoid-islet cell tumor,[14] gastrinoma,[15] and apudoma.[16] The term *apudoma* originated shortly after Pearse[17,18] recognized that endocrine cells were dispersed throughout the body and that these cells shared certain cytochemical and ultrastructural characteristics, including a high *a*mine content, a capability for amine *p*recursor *u*ptake, and the presence of *d*ecarboxylase enzyme (APUD). The name APUD was given to these cells, and the term *apudoma* was used to describe neoplasias or hyperplasias of these cells. All apudomas contain polypeptide hormones, and some are capable of secreting them. The cells of the APUD system and their neoplastic counterparts are found in the pituitary, pineal gland, hypothalamus, pancreas, stomach, intestine, thyroid, parathyroid, carotid body, skin, adrenal glands, lung, and urogenital tract; hence the term *apudoma* is not a morphologic diagnosis but rather a conceptual diagnosis. It does not apply to a specific histologic type of tumor.

Gastrinoma is the clinical term for neuroendocrine (APUD) tumors that secrete gastrin. This diagnosis is based on clinical grounds, including a history of severe peptic ulcer disease, often with complications, and elevated serum gastrin levels. The term *gastrinoma* describes the clinical state of the patient, but it does not define the morphologic and pathologic characteristics of the tumor. It does not indicate whether the tumor is benign or malignant, or whether the tumor arises from pancreatic islet cells (most common site) or from extrapancreatic organs. If the tumor is removed surgically and stained immunochemically, it may show the presence of multiple hormones, including gastrin.[19] The term *carcinoid-islet cell tumor* was therefore proposed in 1967 by Weichert et al[14] because carcinoid tumors and islet cell tumors have similar structures. However, the term *carcinoid-islet cell tumor* has not become popular among either pathologists or surgeons because it adds little to either the pathologic or clinical diagnosis.

Therefore, the term *carcinoid tumor* persists because it is well understood by physicians and it represents a specific histologic diagnosis. Contrary to popular belief, the presence of serotonin in the tumor is not required for the diagnosis of carcinoid tumor; as previously stated, it is rare in carcinoids derived from the foregut. If the clinical presentation suggests the overproduction of a specific vasoactive substance or polypeptide hormone, the tumor can be stained immunochemically for a variety of neuroendocrine markers, including insulin, glucagon, vasoactive intestinal polypeptide, somatostatin, pancreatic polypeptide, and gastrin. The pathologist then reports these neuroendocrine lesions of the gastrointestinal tract as carcinoids with a note indicating the location of the tumor and the immunochemical stains that were performed and whether they were positive or negative. With this in mind, the lesion in our patient can be best described as a gastric (or antral) carcinoid-gastrinoma, which describes both its histologic and clinical features.

In contrast to the benign behavior of carcinoids of the appendix,[20-23] carcinoid tumors in the stomach have a high propensity to metastasize and should be considered potentially malignant. In a review of 2837 carcinoid tumors, Godwin[1] found that 55% of patients with gastric carcinoids had metastases and, subsequently, only 50% survived five years. He also found a 2% incidence of multicentric gastric carcinoids. Several more recent reports have shown a higher incidence of multicentricity (14% to 50%), less frequent metastases (18% to 36%), and longer survival.[6-8,24] Nevertheless, the size of the primary tumor is closely correlated with the incidence of metastases and may have more significance than site of origin. Carcinoids less than 1 cm in diameter have a 2% incidence of metastasis, whereas

those greater than 2 cm are associated with an 80% to 100% incidence of metastases.[22,25]

Since the clinical presentation of patients with a gastric carcinoid can be variable and most patients are asymptomatic or have minimal symptoms, many are found incidentally on barium swallow roentgenograms, upper endoscopy, and laparotomy. In others, an atypical carcinoid syndrome may develop and is characterized by a severe and prolonged vasodilatory facial flush, hypotension, periorbital edema, and lacrimation.[25] Other symptoms, including Zollinger-Ellison syndrome,[9,10] have been reported depending on the biochemically active compounds that are secreted.

Recommended treatment of gastric carcinoid includes wide local excision for small tumors or subtotal gastrectomy for larger lesions; resection of metastasis is recommended in selected patients who are suitable candidates. Metastatic disease is poorly controlled with chemotherapy, but patients with Zollinger-Ellison syndrome can be treated with high-dose histamine receptor blockers or by total gastrectomy, and flushing episodes have been successfully ameliorated by the serotonin antagonists, methysergide and cyproheptadine. In addition, a report[27] on the treatment of Zollinger-Ellison syndrome with somatostatin analogue indicates that this may be a safe, effective method of controlling peptic ulcer diathesis.

The operation we performed in this patient resected the carcinoid, bypassed the gastric outlet obstruction, and permitted spontaneous closure of the choledochoduodenal fistula (the latter most certainly a complication of his duodenal ulcer). His prognosis is good because the tumor was less than 2 cm in diameter and postoperative plasma gastrin level is normal.

CONCLUSION

Gastric carcinoid is a rare clinical entity, and the diagnosis is often difficult and sometimes obscure. However, early and aggressive surgical intervention should improve prognosis and survival of these patients since smaller tumors are less likely to recur or act in a malignant manner.

Calf Deep Venous Thrombosis: A Wolf in Sheep's Clothing?

John T. Philbrick, MD, Daniel M. Becker, MD, MPH

To determine the natural history of calf deep venous thrombosis (C-DVT), an analytic review of the 20 relevant English-language papers published since 1942 was performed. Remarkably little methodologically sound research on this subject was found. However, available evidence suggests that C-DVT propagates to the thigh in up to 20% of cases and that propagation invariably occurs before embolization. No fatal emboli were reported in patients presenting with isolated C-DVT. Traditional anticoagulation treatment with heparin sodium and warfarin sodium of symptomatic patients with C-DVT appears to prevent extension, embolization, and early recurrence. There is no convincing evidence that C-DVT leads to chronic venous insufficiency or whether the risks of anticoagulation exceed the risks of no treatment. As an option to anticoagulation, physicians may choose to follow patients with C-DVT with serial impedance plethysmography, treating only if there is evidence of proximal extension (*Arch Intern Med* 1988;148:2131-2138).

Technique

Fibrin Glue Achieves Hemostasis in Patients With Coagulation Disorders

Harry B. Kram, MD; Ragu C. Nathan, MD; Frederick J. Stafford, MD; Arthur W. Fleming, MD; William C. Shoemaker, MD

• Fibrin glue (FG), made with highly concentrated human fibrinogen and clotting factors, was used to achieve parenchymal organ hemostasis in patients with disordered coagulation secondary to massive transfusion, chronic disease, and disseminated intravascular coagulation; it was effective in controlling liver hemorrhage in seven patients and in the performance of a splenorrhaphy in one other patient. The coagulation profile was grossly abnormal in all patients, and the mean ± SD intraoperative blood loss was 5.1 ± 4.2 L; patients received 14 ± 10 U of blood perioperatively. The amount of FG required to achieve hemostasis varied directly with the extent of injury and intraoperative blood loss ($r = .84$), and all patients with a blood loss greater than 4 L required at least 25 mL of FG to stop bleeding. Two patients died postoperatively secondary to cardiac arrest and adult respiratory distress syndrome. Because FG does not depend on adequate platelet or clotting factor levels to be effective, it is especially useful in patients with parenchymal organ hemorrhage and disordered coagulation.

(*Arch Surg* 1989;124:385-387)

The development of disordered coagulation in the acutely injured patient who requires emergency surgery is associated with increased mortality.[1,2] In addition, the failure to effect intraoperative hemostasis rapidly may result in iatrogenic injury, resulting from attempts to control hemorrhage in an operative field obscured by rapidly pooling blood. Conventional topical hemostatic agents, which enhance normal clotting by providing a matrix around which blood clots can form or entrap platelets, are usually ineffective in the bleeding patient with deficient clotting factors and thrombocytopenia.

The use of highly concentrated human fibrinogen, in combination with thrombin, factor XIII, and calcium chloride, has been shown to result in the formation of a fibrin glue (FG) that is effective in establishing hemostasis of parenchymal organs, sealing anastomoses, and promoting normal wound healing after surgery.[3-7] Moreover, experimental studies revealed that FG was effective in hemostatically sealing vascular graft anastomoses in an anticoagulated canine model.[8] In the present study, FG was used to achieve hemostasis of liver and splenic injuries in patients with disordered coagulation secondary to massive transfusion, chronic disease, and disseminated intravascular coagulation.

MATERIALS AND METHODS

FG

Fibrin glue is made from four components: (1) highly concentrated fibrinogen (total protein approximately 120 mg/mL); (2) aprotinin (3000 KIU/mL) (1 KIU is equivalent to 1.111×10^{-3} trypsin inhibitor U); (3) dried thrombin (500 US [NIH] U/mL) (1 US [NIH] U is comparable with 1 IU of the first national standard); and (4) calcium chloride (400 μmol/mL). The fibrinogen is obtained from human donor plasma. After preheating to 37°C, the fibrinogen is dissolved in aprotinin, and the dried thrombin is reconstituted in calcium chloride. The two solutions are then drawn up into separate syringes that are loaded onto a double-barreled syringe holder designed to mix and apply the components simultaneously. The reconstitution procedure takes ten to 15 minutes, and the components should be used within four hours. The reconstituted adhesive contains 70 to 100 mg/mL of fibrinogen, 2 to 7 mg/mL of fibronectin (cold-insoluble globulin), 10 U/mL of factor XIII (1 U is that amount of factor XIII that is contained in 1 mL of citrated, pooled human plasma), and 35 mg/L of plasminogen.

On application, the components mix to form a clear, viscous solution that firmly adheres to wound surfaces and sets into a white, rubberlike mass within seconds. The adhesive continues to gain in tensile strength over the course of time; 70% of the maximum tensile strength is achieved in ten minutes.[9] During the subsequent course of wound healing, the adhesive slowly dissolves by fibrinolysis and is eventually completely removed from the body; aprotinin is added to slow the fibrinolytic process. The essential reactions after mixing of the components are proteolysis, fibrin cross-linking, and, finally, lysis and absorption of the clot material during the wound-healing process.

Clinical Data

The use of FG to control parenchymal organ hemorrhage was successfully performed in eight patients with coagulation disorders (Figs 1 through 4); the causes of injury are listed in Table 1. The coagulation profile was grossly abnormal in all patients, and the mean ± SD intraoperative blood loss was 5.1 ± 4.2 L; patients received 14 ± 10 U of blood perioperatively. Fibrin glue was used to achieve liver hemostasis in seven patients and in the performance of a splenorrhaphy in one other patient (Table 2). Of the eight patients in the series, seven experienced varying periods of intraoperative hypotension.

RESULTS

Fibrin glue was immediately effective in achieving hemostasis in all patients, including one patient with a 9-L blood loss secondary to a gunshot wound of the liver that failed to be controlled using mattress sutures, microcrystalline collagen, and clamping of the portal vessels (Pringle maneuver). The amount of FG required to achieve hemostasis varied directly with the extent of injury and intraoperative blood loss ($r = .84$), and all patients with a blood loss greater than 4 L required at least 25 mL of FG to stop bleeding (Fig 5).

One patient with continued disseminated intravascular coagulation underwent reexploration because of hemoperitoneum 24 hours after successful resection of a ruptured hepatic tumor and sealing of the resected liver margin with FG; at reexploration, the FG patch was found to be completely intact, and no bleeding source was identified. The patient recovered without rebleeding. One other patient with multiple injuries of the colon, small intestine, stomach, lung, and diaphragm developed multiple intra-

Note that amount of FG used varied directly with extent of hemorrhage ($r = .84$) and that all patients with blood loss greater than 4 L required at least 25 mL of FG to achieve hemostasis.

abdominal abscesses following extensive fecal contamination, cardiac arrest, and multiple operations.

COMMENT

These studies evaluated the efficacy and safety of FG in achieving parenchymal organ hemostasis in patients with coagulation disorders. No complication attributable to FG was seen, and its use was deemed lifesaving in several patients. The amount of FG required to achieve hemostasis was directly related to the extent of injury and blood loss.

Fibrin glue was found to control bleeding of deep, as well as superficial, parenchymal organ injuries. This allows for a wider spectrum of indications for use when compared with conventional topical hemostatic agents made of collagen, gelatin, or cellulose; use of the latter agents is usually limited to superficial capsular tears in easily accessible areas. Packing of hemostatic material into a deep injury may increase the size of the defect or lead to subcapsular hematoma formation.[10] Completely filling in the defect with a fibrin plug, on the other hand, may help to avoid these complications. No cases of intravascular embolization of FG occurred despite its injection into deep wounds; the use of a high thrombin concentration (500 U/mL) in preparing FG results in the adhesive solidifying within seconds of application, avoiding this complication.

Because FG does not depend on adequate platelet or clotting factor levels, it is effective in patients with dilutional or disease-related coagulation disorders. Previous animal studies revealed that FG was superior to oxidized regenerated cellulose in controlling hemorrhage in a heparinized model.[8] Similarly, FG was successful in achieving hemostasis in all patients with coagulation disorders in the present series. In conclusion, FG provides hemostasis of superficial and deep parenchymal organ injuries, reduces the need for parenchymal sutures, is effective in the presence of deficient platelets and clotting factors, has good local and systemic compatibility, and promotes normal wound healing. Its use may be lifesaving in the critically ill surgical patient with exsanguinating parenchymal organ hemorrhage.

The fibrin glue used in this study was supplied as Fibrin Sealant by Immuno AG, Vienna.

Cefotetan-Associated Coagulopathies

To the Editor:—Two patients from our hospital (Hartford [Conn] Hospital) who developed coagulopathies supposedly from cefotetan were recently described in the ARCHIVES.[1] Having had the opportunity to evaluate these cases in detail, and having a view different from that of the author (Dr Holt), we felt obliged to write this letter. While there was a temporal relationship between cefotetan therapy and the development of hypoprothrombinemias in these patients, there were a number of other reasons for the development of coagulopathies (ie, malignant neoplasm, poor nutritional status, concurrent use of agents that effect hemostasis, and renal or hepatic dysfunction).

During cefotetan therapy the nutritional status of both patients deteriorated. The first patient was without oral intake for the initial six days of her eight-day course of treatment with cefotetan and received no enteral feedings or hyperalimentation during this period. The second patient was without oral intake for the majority of his treatment with cefotetan (17 of 27 days) and for the remainder of the period his oral intake was poor. He received hyperalimentation beginning on the 23rd day of therapy. Not surprisingly, both patients had significant weight loss during the initial three weeks of hospitalization (8.2% and 7.7% loss from initial weight, respectively). Moreover, the initial total serum albumin concentrations were low (21 and 23 g/L, respectively) in both patients. The first patient did not have repeated serum albumin concentrations measured until after discontinuation of cefotetan therapy. In the second patient both the serum albumin and total protein concentrations remained abnormally low throughout his hospitalization. This indicates that the nutritional status of both patients was less than optimal immediately before and during cefotetan therapy. Adding to the overall debilitation of the first patient was the presence of metastatic carcinoma.

Each patient received medications that have been proven to effect hemostasis. Parenteral ranitidine (50 mg every eight hours), which can cause thrombocytopenia,[2-5] was administered to both patients concurrent with cefotetan therapy. In fact, in the second case, the platelet count dropped to 93×10^9/L on the fourth day of cefotetan therapy. This patient also received concurrent therapy with dipyridamole, an antiplatelet agent used in the prevention of thromboembolic events.[6]

Evidence of renal dysfunction was present in both patients. Although the serum creatinine level (50 to 60 μmol/L during cefotetan therapy) of the first patient was within normal limits, her estimated creatinine clearance was only 52 mL/min. The estimated creatinine clearance of the second patient during cefotetan therapy was only 36 mL/min.

The initial prothrombin time was slightly elevated just before initiation of cefotetan therapy in the first patient. Her initial coagulation profile showed a prothrombin time of 13.8 s and a partial prothrombin time of 26 s; these values rose to a maximum of 26.2 s and 48 s, respectively, on the seventh day of therapy. Normal limits in patients at Hartford Hospital are 11 to 13 s and less than 38 s, respectively. Values returned to baseline after three daily administrations of 10 mg of phytonadione intramuscularly.

The second patient was transferred to our hospital via helicopter with the preliminary diagnosis of active gastrointestinal tract bleeding secondary to the formation of an aortoduodenal fistula. He received 7 U of packed red blood cells during and immediately after emergency surgery to correct the situation. His hematocrit and hemoglobin level at this time were 0.35 and 120 g/L, respectively (normal values for men range from 0.45 to 0.52 and 130 g/L to 180 g/L, respectively). This patient had high initial coagulation values (ie, prothrombin time of 14.1 s and a partial thromboplastin time of 52 s). Coagulation values maximized on the 12th day of cefotetan therapy at 28 s and 88 s, respectively. During the next two weeks transfusions were given every few days, for a total of 6 U of packed red blood cells. The hematocrit and hemoglobin level continued to decline during this period to minimum values just before the second surgery of 0.21 and 73 g/L, respectively.

This led us to conclude that the patient had a small, active bleeding process occurring throughout this two-week interval. Providing further support for this view was the need to oversew a suture on a small vessel during the patient's second surgery and the return of the hematocrit to baseline after the patient received an additional 8 U of packed red blood cells and 4 U of fresh-frozen plasma during or immediately after surgery.

In brief, from our independent review of these two cases, cefotetan played a minor role in their bleeding problems.

Effect of β-Adrenergic Blockade on the Growth Rate of Abdominal Aortic Aneurysms

To the Editor:—I read the recent article in the ARCHIVES by Leach et al[1] with great interest. The effect of propranolol hydrochloride on other types of aneurysmal disease could also be explored. For example, the incidence of coronary artery aneurysms in a coronary artery surgery study of 20 087 patients was 5%.[2] The cause was primarily atherosclerotic or congenital, with over half secondary to atherosclerosis. The main complica-

tions reported were rupture with sudden death, thrombosis, and myocardial infarction secondary to embolization. Medical treatment generally consists of the use of antithrombotic drugs. Often a patient has associated coronary artery stenosis and poststenotic dilation and aneurysm formation. Often these patients are receiving propranolol for treatment of associated disease, such as hypertension, angina pectoris, and the control of certain types of cardiac arrhythmias. Therefore, in a large medical center such as Yale (New Haven, Conn), where many coronary angiographic studies are done, patients with coronary artery aneurysms could participate in a prospective clinical study with propranolol and be followed up angiographically. Recent coronary aneurysm studies[3] in Japan on patients with a history of Kawasaki disease have examined the distensibility of coronary aneurysms with the vasodilator dipyridamole and found a decrease in the distensibility when compared with normal coronary arteries. Distensibility studies could be combined with propranolol treatment studies. Another potential area of interest is treatment of intracranial aneurysms with propranolol, because connective-tissue disorders and hypertension may contribute to the causation of intracranial aneurysms.

Spontaneous Renal Rupture in Pregnancy

To the Editor.—Spontaneous renal rupture is a rare complication of pregnancy, but is hazardous to both the mother and the infant. It seems hardly possible to initially diagnose spontaneous renal rupture in a pregnant woman, mainly because it presents the symptoms of acute abdomen, and because the incidence of the disease is rare. We report a case of a pregnant women with spontaneous renal rupture in whom renal arteriography confirmed the diagnosis.

Report of a Case.—A 31-year-old pregnant woman, in the third trimester, was admitted to the hospital on June 15, 1986, because of severe left flank pain of sudden onset that was accompanied by shock.

When she recovered from the shock by means of multiple infusions, her blood pressure was 134/80 mm Hg, and her heart rate was 90 beats per minute. Fetal heart sounds were not audible. Marked tenderness was found in the lower left abdominal quadrant and left flank. There was no vaginal bleeding or discharge. The chest roentgenogram showed a mild left pleural effusion.

She denied having any recent blunt trauma to her back or abdomen. She reported no blood in her stool or urine, and showed no urinary symptoms. This was her first pregnancy.

A complete blood cell count yielded the following: red blood cell count, 2.2×10^{12}/L; white blood cell count, 19.0×10^{9}/L; hemoglobin level, 61 g/L; and hematocrit, 0.192. Urinalysis showed occasional red blood cells and no white blood cells per high-power field.

The provisional diagnosis of premature separation of the normally implanted placenta causing intrauterine fetal death was made. On June 16, she delivered vaginally a dead male infant weighing 1940 g. Four days after admission, she again complained of abdominal pain, accompanied by the progression of anemia. Computed tomography of the abdomen disclosed an extensive retroperitoneal hematoma around the left kidney (Fig 1). The left kidney was not seen on the intravenous pyelogram. Blood transfusions maintained her circulatory stability, but on June 25, she once again became hemodynamically unstable with further progression of anemia and an increase of abdominal circumference. For the detection of the bleeding origin, aortography and left renal arteriography were performed (Fig 2). The renal arteriography elucidated a large subcapsular hematoma of the left kidney. A left-sided nephrectomy and drainage of the retroperitoneal giant hematoma were urgently performed.

The left kidney measured 25 cm from the upper pole to the lower pole, 15 cm in frontal diameter, and 10 cm in sagittal diameter. The capsule ruptured at the lower pole. Pathologically, arterial malformation of the kidney was suspected.

Postoperatively, the course of recovery was uneventful.

Comment.—Retroperitoneal hemorrhage originating from spontaneous rupture of the kidney should be considered as a differential diagnosis of acute abdomen in pregnancy.[1] However, as the incidence of the disease in pregnant women seems extremely small, the correct diagnosis can hardly be obtained preoperatively, according to reported cases in the English literature.[1,2] In our case, the diagnosis was confirmed by renal arteriography, which had been performed during the hemodynamically unstable period. We feel that renal arteriography can be safely performed to establish the diagnosis of spontaneous renal rupture in pregnancy.

Fig 1.—Computed tomogram of abdomen. Large retroperitoneal hematoma is present around left kidney.

Fig 2.—Renal arteriogram showing left renal trunk shifted cephalad (arrow). Capsular arterial branches (asterisks) run away from renal parenchyma, suggesting large subcapsular hematoma.

Renal arteriography is an informative diagnostic tool useful in treating a pregnant woman who has retroperitoneal hematoma.

Books

Essentials of Surgery, edited by Peter F. Lawrence, Merril Dayton, Richard Bell, and Marcia Bilbao, 410 pp, $27, Baltimore, Williams & Wilkins, 1988.

Any attempt by experienced surgeons to improve methods of teaching medical students deserves serious examination. This book, edited by surgeons from the University of Utah and a radiologist from the University of South Carolina, so qualifies. The softcover book is the core of a multimedia effort by members of the Association of Surgical Education to combine modern teaching techniques with new technology for better medical education. The 88 authors of this book are primarily young academic surgeons who are concerned about this frequently neglected responsibility of academic surgery. The book brings back memories of three decades ago when some of us introduced educational subjects for the first time into the program of the Society of University Surgeons and created a Committee on Surgical Education.

The authors are, for a change, not the old guard whose names are usually associated with textbook chapters. In their place is the younger generation of experts. The result is refreshing and innovative.

The textbook is the core of the multimedia program around which the editors have created a variety of peripherals that can be purchased separately. The book itself is relatively inexpensive ($27), but the entire package costs $1900. For this considerable sum one gets all the technical props needed for teaching medical students, including videotapes for teaching essential surgical skills, a computer software package of patient management problems, a bank of 1100 written questions, a group of multiple-choice questions intended for use in an oral examination, and a set of 198 35-mm slides to be used in lecture presentations.

Only about 10% of all medical students will end up practicing surgery or a surgical specialty. The challenge in writing a text for students is to identify the concepts and data important for all students. This involves identifying principles and omitting nonessentials. In general, *Essentials of Surgery* is remarkably successful due to Lawrence's preliminary survey of a wide variety of surgeons asking them what they considered essential for students to learn. The authors were well briefed, I am certain, before they signed on. A few seemed to ignore their fathometer and either plunged too deeply or remained too near the surface of their assigned subject.

A case in point is the question of what data a student should know concerning surgical disease and management. It seems to me that three sets of data so qualify. First, what are the numbers defining normalcy? These, like multiplication tables, simply must be memorized or be kept at hand. The second aspect pertains to frequency, which is difficult to understand until one can establish by experience a personal database. What diseases occur frequently and what are the signs and symptoms associated with them? Not yet within the curriculum but, in my opinion, soon to be included are the performance characteristics of diagnostic tests. The third type of data is a numerical characteristic of prognosis. Undoubtedly, some harsh editorial supervision was needed to achieve the proper subject depth for students. Perhaps that is why the editors selected young colleagues as authors. One problem with the book is that there are too many authors (88) for this 410-page volume. Some of the chapters have detectable crevices where one author left off and another took over.

An appealing feature of the book is its limited length. This is in contrast to the current trend in textbooks, which increasingly have come to resemble hardcover dinosaurs, understandably frightening away many students. This book can be read and understood within the limited time now available in most medical school curricula devoted to surgery.

As the title of the book indicates, this volume covers general surgery, which quite properly is the core of medical student teaching. I understand that a subsequent volume is being prepared for surgical specialties.

Each chapter, be it devoted to a general subject or to a specific disease or anatomic area, is similarly organized. This makes it easier to read and check references. The first part of each chapter contains a short paragraph entitled "Assumptions." These are what the student is expected to know before proceeding. Next comes a highlighted half page entitled "Objectives." This skeleton is fleshed out in the bulk of the chapter that follows. At the end of each chapter are the feathers and appendages: a list of essential operative skills and often descriptions of how to perform them, a list of no more than 20 references for in-depth reading, and, finally, some study questions. The book has a nonthreatening "user-friendly" tone.

The text is liberally sprinkled with good algorithms, which, like most of the tables, are well chosen and clean. Line drawings are good, except for some glaring exceptions (eg, the chapter on the small bowel). The quality of x-ray reproductions and their descriptive legends varies.

The book starts with a chapter on health care issues, a trend that reflects the interests of modern students. I was disappointed that there was only passing reference to surgical decision making. Perhaps the editors assumed that students were familiar with this important aspect of clinical medicine. If they made such an assumption, they were mistaken!

This is an important and imaginative book for medical students and those responsible for their surgical education. Taken alone it will be a valuable textbook for junior and senior students. Purchased with its peripherals of slides, tapes, and computer software, it will be expensive but valuable.

Teaching is an art as well as a science, but as with other art forms, the best master the scientific fundamentals. *Essentials of Surgery* demonstrates modern trends in surgical education for medical students.

Liver Transplantation: Clio Chirurgica, by T. E. Starzl, C. G. Groth, and L. McKowka, 363 pp, $45, Austin, Texas, Silvergill Inc, 1988.

Carlyle believed that unique individuals are of prime importance in shaping the course of human history. It was a theory of history much in vogue during the Victorian era but was superseded by an emphasis on economic and political power as determinants. Carlyle's thesis is debatable for history in general, but few can doubt the importance of unique individuals in changing the course of surgical history. Carlyle calls the historic leaders "heroes." Starzl, the senior author of this volume, and Roy Calne are, of course, the two heroes who have taken liver transplantation from theory to clinical reality.

Clio was the Greek goddess of history and this book is one of a series of monographs each devoted to the history of some aspect of surgery. It is unique in that the entire history of

liver transplantation is concentrated within 25 years.

Starzl and his colleagues provide 41 seminal articles that trace the development of liver transplantation. Each is put in its historic perspective by a few pages of commentary, which indicates the question the reported laboratory or clinical data answers and how the article provided a step forward. The connecting commentaries provide a balance of scholarly reporting and personal interests of those who contributed.

It is difficult for those of us who lived through and, in various ways, participated in this exciting era of surgical advancement to be dispassionate by either the way that progress was made or the exciting personalities involved. Scientific progress made at this breakneck speed is usually controversial and surrounded by great excitement. Reading this or any other history of science, one finds that each new step seems to be a logical progression of that which went before. Those who participated, however, know this is far from fact. Many blind alleys, such as plasmapheresis, lymph duct drainage, or splenectomy, were probed at a great expenditure of time, energy, and money before being abandoned. A good scientist knows when to quit as well as when to press on in the dogged fashion that characterizes those who advanced liver transplantation. Not recorded in this history of liver transplantation are the harsh comments of deans, hospital administrators, the press, and even lesser faculty members "bumped" from the operating schedule when a patient receiving a transplant needed care. Many eggs and egos were broken in making the transplantation omelette.

The authors demonstrated good judgment in the selection of papers to be reprinted and photographs of the contributing pioneers. Several unsung contributors were mentioned. One example is Jack Cannon whose paragraph in the 1956 *Transplantation Bulletin* suggested that liver transplantation might someday be possible. Another appropriate homage went to Stewart Welch, who, though unsuccessful, pioneered liver transplants in animals.

An obvious question is how the Pittsburgh group of editors handled the almost equally important contributions of Calne and his colleagues in Cambridge and London. The two groups have been neck and neck in an exciting scientific race for 25 years. Only four of the 41 articles chosen for reprint were written by Sir Roy Calne. However, Starzl, Groth, and McKowka give effusive praise and recognition to Calne and simply admit that it would not be possible to include all of his contributions. It is a reflection of the friendly rivalry that has existed between Starzl and Calne over two decades. Invariably, they shared their experiences with each other so that the most efficient rate of progress could be made. It is a relationship of which surgery can be proud.

At best, history has two benefits: it records events and by accurately tracing the pattern by which events occur helps us understand how progress can be made. This book has worth on both counts. It illustrates how talented, well-trained, disciplined, and dedicated people can develop ideas and turn them into reality. To those of us who knew both groups of players in this exciting field, it also illustrates how dogged dedication to an idea can prove successful.

One can only pity students of surgery who cannot be a part of a scientific environment on the cutting edge of surgical progress. Sharing, even vicariously, the excitement of progress broadens the young surgeon's entire education. Providing such excitement is one of the many contributions made by the authors of this book. It is the highest form of education.

Accepted wisdom in the press emphasizes "breakthroughs" in science as though everything is at a standstill until one day a brilliant new idea strikes an investigator, who, in one form or another, shouts "Eureka!" and proclaims his idea to the world. Such nonsense is dispelled by this carefully documented scholarly history of liver transplantation. Progress is slow, hesitating, and frustrating even by such heroes as those who wrote this book.

The Surgery Boards Review Course

April 24-30 and October 4-10, 1989 – Chicago
September 18-24, 1989 – Rochester, NY
October 30-November 5, 1989 – Philadelphia

Now, a special update for your written or recertification or oral exam

OBJECTIVES:
- To increase knowledge of surgical principles and practice
- To prepare candidates to take written and oral board exams
- To provide a comprehensive review for recertification

METHODS:
- HOME STUDY MATERIALS consisting of a syllabus of questions and answers with assignments
- SEMINAR with projection slides and syllabus

*"The faculty was outstanding. The most pleasant thing was learning a tremendous amount, not only from world-famous authorities but from people who are relatively unknown as well."**

*"Accommodations were comfortable..."**

GOALS AND LOCATION: The course is to help you pass your written and oral, or recertification exams. Sites are chosen for excellent study and minimal cost of hotel and travel for board candidates. Home study questions will be sent before the course. Your best value is to repeat the seminar for half price the week before both written and oral exams. Topics and faculty are upgrades for each program. Our hotel rates are typically $66 to $80 single and $80 and $98 double. Please wait for instructions before buying travel tickets.

*"...and those little extras...."**

LOWEST AIR FARES: Reliable Travel offers you the lowest air fare – often below super-saver rates. Please call toll-free 1-800-645-6504 ext. 10 and identify yourself with this Osler course for special group fares.

*"...remarkably complete and pleasant."**

PLACEMENT SERVICE: For a practice opportunity write or call (800) 356-7537.

*"...the most education for the money."**

FEES AND C.M.E. CREDITS:
- **C.M.E. Credits Hours: 65 hrs.**
- Practicing Surgeon: $720
- Resident or Fellow: one third off
- Repeating course within 3 years: half price
- **Add 10% within 10 days of the course.**
- Attendees not in course hotel add $8/day.
- Fees include no lodging or meals.
- $50.00 will reserve your position.
- Most home study materials will be mailed after half of registration fee is received.

*"...home study material was extremely helpful."**

CANCELLATIONS: Refunds subject to $50 fee, will be made until the seminar begins.
- Cancellation after mailing home study material requires retention of half of the fee.

*"I feel [the course] helped me pass the boards."**

CEFOTAN® IM/IV (cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri*, and *Morganella morganii*).
Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.
Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis,* Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.
Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis,* Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).
Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).
Bone and joint infections caused by *Staphylococcus aureus*.†
***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.
† Efficacy for this organism in this organ system was studied in fewer than ten infections.
PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be

developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes: Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21).

Rocephin® ROCHE® IV·IM

ceftriaxone sodium/Roche

Before prescribing, please consult complete product information, a summary of which follows:

INDICATIONS AND USAGE: Rocephin is indicated for the treatment of the following infections when caused by susceptible organisms:

LOWER RESPIRATORY TRACT INFECTIONS caused by *Strep. pneumoniae, Streptococcus* species (excluding enterococci), *Staph. aureus, H. influenzae, H. parainfluenzae, Klebsiella* species (including *K. pneumoniae*), *E. coli, E. aerogenes, Proteus mirabilis* and *Serratia marcescens*.

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus, Staph. epidermidis, Streptococcus* species (excluding enterococci), *E. cloacae, Klebsiella* species (including *K. pneumoniae*), *Proteus mirabilis* and *Pseudomonas aeruginosa*.

URINARY TRACT INFECTIONS (complicated and uncomplicated) caused by *E. coli, Proteus mirabilis, Proteus vulgaris, M. morganii* and *Klebsiella* species (including *K. pneumoniae*).

UNCOMPLICATED GONORRHEA (cervical/urethral and rectal) caused by *Neisseria gonorrhoeae*, including both penicillinase and nonpenicillinase producing strains.

PELVIC INFLAMMATORY DISEASE caused by *N. gonorrhoeae*.

BACTERIAL SEPTICEMIA caused by *Staph. aureus, Strep. pneumoniae, E. coli, H. influenzae* and *K. pneumoniae*.

BONE AND JOINT INFECTIONS caused by *Staph. aureus, Strep. pneumoniae, Streptococcus* species (excluding enterococci), *E. coli, P. mirabilis, K. pneumoniae* and *Enterobacter* species.

INTRA-ABDOMINAL INFECTIONS caused by *E. coli* and *K. pneumoniae*.

MENINGITIS caused by *H. influenzae, N. meningitidis* and *Strep. pneumoniae*. Ceftriaxone has also been used successfully in a limited number of cases of meningitis and shunt infections caused by *Staph. epidermidis* and *E. coli*.

SURGICAL PROPHYLAXIS: Preoperative administration of a single 1 gm dose may reduce incidence of postoperative infections in patients undergoing surgical procedures classified as contaminated or potentially contaminated (*e.g.*, vaginal or abdominal hysterectomy) and in those for whom infection at the operative site presents serious risk (*e.g.*, during coronary artery bypass surgery).

Although ceftriaxone has been shown to have been as effective as cefazolin in the prevention of infection following coronary artery bypass surgery, no placebo-controlled trials have been conducted to evaluate any cephalosporin antibiotic in the prevention of infection following coronary artery bypass surgery. When administered before indicated surgical procedures, a single 1 gm dose provides protection from most infections due to susceptible organisms for duration of procedure.

SUSCEPTIBILITY TESTING: Before instituting treatment with Rocephin, appropriate specimens should be obtained for isolation of the causative organism and for determination of its susceptibility to the drug. Therapy may be instituted prior to obtaining results of susceptibility testing.

CONTRAINDICATIONS: Rocephin is contraindicated in patients with known allergy to the cephalosporin class of antibiotics.

WARNINGS: BEFORE THERAPY WITH ROCEPHIN IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE WHETHER THE PATIENT HAS HAD PREVIOUS HYPERSENSITIVITY REACTIONS TO CEPHALOSPORINS, PENICILLINS OR OTHER DRUGS. THIS PRODUCT SHOULD BE GIVEN CAUTIOUSLY TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE THE USE OF SUBCUTANEOUS EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind to the toxin *in vitro*.

Mild cases of colitis respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte and protein supplementation as indicated.

When the colitis is not relieved by drug discontinuance or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C. difficile*. Other causes of colitis should also be considered.

Rarely, shadows suggesting sludge have been detected by sonograms of the gallbladder in asymptomatic and symptomatic patients. This appears to be reversible on discontinuation of therapy. In a few symptomatic patients receiving higher than usual doses, who underwent surgery, sludge containing traces of ceftriaxone was recovered from surgical specimens. Discontinue therapy in patients who develop signs or symptoms suggestive of gallbladder disease; consider conservative management.

PRECAUTIONS: *GENERAL:* Although transient elevations of BUN and serum creatinine have been observed, at the recommended dosages, the nephrotoxic potential of Rocephin is similar to that of other cephalosporins.

Ceftriaxone is excreted via both biliary and renal excretion (see Clinical Pharmacology). Therefore, patients with renal failure normally require no adjustment in dosage when usual doses of Rocephin are administered, but concentrations of drug in the serum should be monitored periodically. If evidence of accumulation exists, dosage should be decreased accordingly.

Dosage adjustments should not be necessary in patients with hepatic dysfunction; however, in patients with both hepatic dysfunction and significant renal disease, Rocephin dosage should not exceed 2 gm daily without close monitoring of serum concentrations.

Alterations in prothrombin times have occurred rarely in patients treated with Rocephin. Patients with impaired vitamin K synthesis or low vitamin K stores (*e.g.*, chronic hepatic disease and malnutrition) may require monitoring of prothrombin time during Rocephin treatment. Vitamin K administration (10 mg weekly) may be necessary if the prothrombin time is prolonged before or during therapy.

Prolonged use of Rocephin may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection occurs during therapy, appropriate measures should be taken.

Rocephin should be prescribed with caution in individuals with a history of gastrointestinal disease, especially colitis.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Carcinogenesis: Considering the maximum duration of treatment and the class of the compound, carcinogenicity studies with ceftriaxone in animals have not been performed. The maximum

ROCEPHIN® (ceftriaxone sodium/Roche)

duration of animal toxicity studies was six months.

Mutagenesis: Genetic toxicology tests included the Ames test, a micronucleus test and a test for chromosomal aberrations in human lymphocytes cultured *in vitro* with ceftriaxone. Ceftriaxone showed no potential for mutagenic activity in these studies.

Impairment of Fertility: Ceftriaxone produced no impairment of fertility when given intravenously to rats at daily doses up to 586 mg/kg/day, approximately 20 times the recommended clinical dose of 2 gm/day.

PREGNANCY: Teratogenic Effects: Pregnancy Category B. Reproductive studies have been performed in mice and rats at doses up to 20 times the usual human dose and have no evidence of embryotoxicity, fetotoxicity or teratogenicity. In primates, no embryotoxicity or teratogenicity was demonstrated at a dose approximately three times the human dose. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nonteratogenic Effects: In rats, in the Segment I (fertility and general reproduction) and Segment III (perinatal and postnatal) studies with intravenously administered ceftriaxone, no adverse effects were noted on various reproductive parameters during gestation and lactation, including postnatal growth, functional behavior and reproductive ability of the offspring, at doses of 586 mg/kg/day or less.

NURSING MOTHERS: Low concentrations of ceftriaxone are excreted in human milk. Caution should be exercised when Rocephin is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness of Rocephin in neonates, infants and children have been established for the dosages described in the Dosage and Administration section. *In vitro* studies have shown ceftriaxone, like some other cephalosporins, can displace bilirubin from serum albumin. Exercise caution before administration to hyperbilirubinemic neonates, especially prematures.

ADVERSE REACTIONS: Rocephin is generally well tolerated. In clinical trials, the following adverse reactions, which were considered to be related to Rocephin therapy or of uncertain etiology, were observed:

LOCAL REACTIONS—pain, induration or tenderness at the site of injection (1%). Less frequently reported (less than 1%) was phlebitis after I.V. administration.

HYPERSENSITIVITY—rash (1.7%). Less frequently reported (less than 1%) were pruritus, fever or chills.

HEMATOLOGIC—eosinophilia (6%), thrombocytosis (5.1%) and leukopenia (2.1%). Less frequently reported (less than 1%) were anemia, neutropenia, lymphopenia, thrombocytopenia and prolongation of the prothrombin time.

GASTROINTESTINAL—diarrhea (2.7%). Less frequently reported (less than 1%) were nausea or vomiting, and dysgeusia.

HEPATIC—elevations of SGOT (3.1%) or SGPT (3.3%). Less frequently reported (less than 1%) were elevations of alkaline phosphatase and bilirubin.

RENAL—elevations of the BUN (1.2%). Less frequently reported (less than 1%) were elevations of creatinine and the presence of casts in the urine.

CENTRAL NERVOUS SYSTEM—headache or dizziness were reported occasionally (less than 1%).

GENITOURINARY—moniliasis or vaginitis were reported occasionally (less than 1%).

MISCELLANEOUS—diaphoresis and flushing were reported occasionally (less than 1%).

Other rarely observed adverse reactions (less than 0.1%) include leukocytosis, lymphocytosis, monocytosis, basophilia, a decrease in the prothrombin time, jaundice, gallbladder sludge, glycosuria, hematuria, anaphylaxis, bronchospasm, serum sickness, abdominal pain, colitis, flatulence, dyspepsia, palpitations and epistaxis.

DOSAGE AND ADMINISTRATION: Rocephin may be administered intravenously or intramuscularly. The usual adult daily dose is 1 to 2 gm given once a day (or in equally divided doses twice a day) depending on the type and severity of the infection. The total daily dose should not exceed 4 grams.

For the treatment of serious miscellaneous infections in children, other than meningitis, the recommended total daily dose is 50 to 75 mg/kg (not to exceed 2 grams), given in divided doses every 12 hours.

Generally, Rocephin therapy should be continued for at least two days after the signs and symptoms of infection have disappeared. The usual duration is 4 to 14 days, in complicated infections longer therapy may be required.

In the treatment of meningitis, a daily dose of 100 mg/kg (not to exceed 4 grams), given in divided doses every 12 hours, should be administered with or without a loading dose of 75 mg/kg.

For the treatment of uncomplicated gonococcal infections, a single intramuscular dose of 250 mg is recommended.

For preoperative use (surgical prophylaxis), a single dose of 1 gm administered 1/2 to 2 hours before surgery is recommended.

When treating infections caused by *Streptococcus pyogenes*, therapy should be continued for at least ten days.

No dosage adjustment is necessary for patients with impairment of renal or hepatic function; however, blood levels should be monitored in patients with severe renal impairment (*e.g.*, dialysis patients) and in patients with both renal and hepatic dysfunctions.

HOW SUPPLIED: Rocephin (ceftriaxone sodium/Roche) is supplied as a sterile crystalline powder in glass vials and piggyback bottles. The following packages are available:

Vials containing 250 mg, 500 mg, 1 gm or 2 gm equivalent of ceftriaxone, piggyback bottles containing 1 gm or 2 gm equivalent of ceftriaxone; bulk pharmacy containers containing 10 gm equivalent of ceftriaxone (NOT FOR DIRECT ADMINISTRATION)

Also supplied as a sterile crystalline powder as follows:
ADD-Vantage Vials** containing 1 gm or 2 gm equivalent of ceftriaxone.

Also supplied premixed as a frozen iso-osmotic, sterile, nonpyrogenic solution of ceftriaxone sodium in 50 mL single dose plastic containers,† as follows:

1 gm equivalent of ceftriaxone, iso-osmotic with approximately 1.9 gm dextrose hydrous, USP added.

2 gm equivalent of ceftriaxone, iso-osmotic with approximately 1.2 gm dextrose hydrous, USP added.

NOTE: Rocephin in the frozen state should not be stored above -20°C.

Nutley, New Jersey 07110-1199

METROPOLITAN WASHINGTON, D.C.

Board Certified or Eligible Thoracic, Vascular, Plastic, Neuro and General Surgeons wanted to join a multi-specialty group practice. Group serving 250,000 members of Kaiser Permanente of the Mid-Atlantic States Region. Busy surgical practice. Excellent salary and benefit package. Send CV with all inquiries to:

William J. McAveney, M.D.
Physician Recruitment Director
Capital Area Permanente Medical Group, P.C.
4200 Wisconsin Avenue, N.W.
Suite 300
Washington, D.C. 20016

GENERAL/THORACIC SURGEON NEEDED

BC/E. Opportunity to establish excellent private practice with no investment, guaranteed income. Growing service area population is now 90,000. 112 bed full service hospital. Located in Central California near Sequoia National Park, Tulare offers family oriented environment, abundant and varied outdoor recreation, beautiful homes attractively priced, good schools, restaurants, services and shopping. New businesses are contributing to the steady growth of our active community where the lifestyle advantages of a small city are combined with easy access to all California's major cities and attractions. For information, please send CV or call-

Tulare District Hospital

VASCULAR SURGEON

BC/BE Vascular Surgeon to join surgical department of thirty-three physician group practice located in historic town near Washington, D.C. and Richmond, VA. Surgical department currently consists of: General/Thoracic Surgeon, Otorhinolaryngologist, Urologist, Orthopedic Surgeons, and OB/GYNs with Surgical Oncologist to join in summer. Practice includes operational non-invasive vascular laboratory. Salary is productivity-based; partnership available after one year. Excellent quality of life in area near beaches, mountains, and rivers.

COBE *BRAT*™—The fastest, most versatile way to meet all of your autologous blood salvage demands.

When surgeons wanted maximum speed in RBC turnaround, they developed their own autotransfusion system. Then perfected it at the Baylor College of Medicine and the Methodist Hospital in Houston. And to ensure its versatility in all types of procedures, they turned to COBE/Kardiothor.

The unique BRAT (Baylor Rapid Autologous Transfusion) System gives you more RBCs faster. When you need them most. In major trauma, open heart, vascular, and emergency procedures.

Its innovative centrifuge bowl design provides consistently higher hematocrits (averaging more than 50%) and excellent heparin removal. Plus, a special, built-in reinfusion protection system provides an added measure of safety during use, allowing *reinfusion under pressure in critical situations.*

Maybe that's why the BRAT autotransfusion system is *the* choice among surgeons at major medical centers today. And why the BRAT offers the RBC quality, speed, and versatility of an autotransfusion system you might have designed yourself.

For more information, call *1-800-622-BRAT* or *1-800-525-COBE.*

The Veterans Administration and Surgical Education in the United States 407
James M. Guernsey, MD, FACS, Martinez, Calif

PAPERS READ BEFORE THE 12TH ANNUAL SURGICAL SYMPOSIUM OF THE ASSOCIATION OF VETERANS ADMINISTRATION SURGEONS, MINNEAPOLIS, MINN, MAY 12 TO MAY 16, 1988

Common Bile Duct Healing: Do Different Absorbable Sutures Affect Stricture Formation and Tensile Strength? 408
Kenneth W. Sharp, MD; Charles B. Ross, MD; Vicki N. Tillman; John F. Dunn, MD, Nashville, Tenn
- The type of absorbable suture used had no effect on the anastomotic strictures or breaking strength of a common bile duct anastomosis.

Epidural Anesthesia in Patients Undergoing Thoracic Surgery 415
Barbara K. Temeck, MD; Paul W. Schafer, MD; Woo Y. Park, MD; John W. Harmon, MD, Washington, DC
- Epidural anesthesia with light general anesthesia was quite satisfactory in high-risk patients requiring thoracotomies.

Use of Sequential B-Mode Ultrasonography to Manage Abdominal Aortic Aneurysms 419
Fred N. Littooy, MD, Maywood, Ill; George Steffan, PA, Hines, Ill; Howard P. Greisler, MD, Maywood, Ill; Theresa L. White, RN, Hines, Ill; William H. Baker, MD, Maywood, Ill
- A threshold of 5 cm in diameter to consider elective repair remains feasible.

Pelvic Fracture Hemorrhage: Priorities in Management 422
B. Mark Evers, MD; Henry M. Cryer, MD; Frank B. Miller, MD, Louisville, Ky
- Patients continue to die of pelvic fracture hemorrhage despite angiography, embolization, MAST, and external fixation.

Anastomotic Tensile Strength Following In Situ Replacement of an Infected Abdominal Aortic Graft 425
Raymond Vetsch, MD; Dennis F. Bandyk, MD; David D. Schmitt, MD; Thomas M. Bergamini, MD; James D. Storey, MD; Jonathan B. Towne, MD, Milwaukee, Wis
- Replacement of infected canine aortic grafts resulted in satisfactory healing.

Hemodynamic Effects on Endothelial Cell Monolayer Detachment From Vascular Prostheses 429
Howard P. Greisler, MD; Eric D. Endean, MD; John J. Klosak, MD, Maywood, Ill; Joan Ellinger, Scott C. Henderson, Hines, Ill; Si M. Pham, MD; Steven J. Durham, MD; David P. Showalter, MD; Jeffery Levine, PhD; Harvey S. Borovetz, PhD, Pittsburgh, Pa
- Cultured endothelial cells remained adherent to graft surfaces during artificial flow states.

Pentoxifylline Increases Extremity Blood Flow in Diabetic Atherosclerotic Patients 434
Richard W. Schwartz, MD; Nancy M. Logan; Paul J. Johnson, MD; William E. Strodel, MD; Joseph G. Fine, MD; Andris Kazmers, MD; Gordon L. Hyde, MD, Lexington, Ky
- In eight of ten patients there was an increase in dorsalis pedis arterial flow.

Microvascular Free-Tissue Transfer: The Atlanta Veterans Administration Medical Center Experience 438
Grant W. Carlson, MD, John J. Coleman III, MD, Atlanta, Ga
- Free microvascular tissue transfer effectively solved many reconstruction and wound problems. Results improved with increased experience.

The Role of Isolated Profundaplasty for the Treatment of Rest Pain 441
David M. McCoy, MD; Alan P. Sawchuk, MD; James J. Schuler, MD; Joseph R. Durham, MD; Jens Eldrup-Jorgensen, MD; Thomas H. Schwarcz, MD; Joseph P. Meyer, MD; D. Preston Flanigan, MD, Chicago, Ill
- Isolated profundaplasty was beneficial in 57% of patients but this could have been increased if selection had been based on hemodynamic measurements.

Recombinant Human Tumor Necrosis Factor Produces Hemodynamic Changes Characteristic of Sepsis and Endotoxemia 445
William J. Schirmer, MD; James M. Schirmer; Donald E. Fry, MD, Cleveland, Ohio
- Injection of human TNF in rats produced the hyperdynamic changes of sepsis with reduced hepatic blood flow.

The **ARCHIVES OF SURGERY** (ISSN 0004-0010) is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago, IL 60610 and at additional mailing office.

SUBSCRIPTION RATES—The subscription rates for the ARCHIVES OF SURGERY are as follows: $50 for one year, $85 for two years in the United States and US possessions; all other countries, one year, $60; two years, $105 for surface delivery. (For expedited air delivery to most countries, add $15 surcharge for one-year subscription, $30 for two years.) Rates for subscriptions for delivery to Japan or South Korea are available through exclusive agents—contact the publisher. ***Special rates for residents and medical students in the United States and US possessions are available.*** Address inquiries to the American Medical Association, Circulation and Fulfillment Division, 535 N Dearborn St, Chicago, IL 60610. Phone: (312) 280-7168.

CHANGE OF ADDRESS—POSTMASTER, send all address changes to ARCHIVES OF SURGERY. Attention: Subscription Department, 535 N Dearborn St, Chicago, IL 60610. Notification of address change must be made at least six weeks in advance, include both old and new addresses, a recent mailing label, and your new zip code.

ADVERTISING PRINCIPLES: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. The appearance of advertising in AMA publications is not an AMA guarantee or endorsement of the product or the claims made for the product by the manufacturer.

CONTENTS—Continued

The Association of *Escherichia coli* Virulence and Pulmonary Microvascular Damage 449
Roderick A. Barke, MD; David L. Dunn, MD, PhD; Agustin P. Dalmasso, MD; Melody O'Connor-Allen, MD; Richard L. Simmons, MD; Edward W. Humphrey, MD, PhD, Minneapolis, Minn
- Increased virulence of organisms was associated with increased lung microvascular damage.

Effect of Eflorithine on Intestinal Regeneration 454
Jon S. Thompson, MD; Shailendra K. Saxena, MD, MS; John G. Sharp, PhD, Omaha, Neb
- Inhibition of polyamine synthesis impaired growth of new intestinal mucosa.

Effective Hepatic Blood Flow During Cardiopulmonary Bypass 458
William W. Hampton, MD; Michael C. Townsend, MD; William J. Schirmer, MD; David M. Haybron, MD; Donald E. Fry, MD, Cleveland, Ohio
- Effective hepatic blood flow was decreased in patients during cardiopulmonary bypass.

Concomitant Cholecystectomy for Asymptomatic Cholelithiasis 460
Larry E. Bragg, MD, Jon S. Thompson, MD, Omaha, Neb
- Incidental cholecystectomy is recommended in patients with asymptomatic gallstones who require a laparotomy for other reasons.

Reversal of Pigment Gallstone Disease in a Canine Model 463
Lillian G. Dawes, MD; David L. Nahrwold, MD; Sanford I. Roth, MD; Robert V. Rege, MD, Chicago, Ill
- Dietary-induced pigment gallstones disappeared following discontinuation of the lithogenic diet in dogs.

Terminal Loop Cutaneous Ureterostomy in Cadaveric Kidney Transplantation 467
R. Neal Garrison, MD; Frederick R. Bentley, MD; Mohammad Amin, MD, Louisville, Ky
- Terminal loop cutaneous ureterostomy is a safe, effective means of urinary drainage in kidney transplantation when the bladder cannot be used.

Pentagastrin Stimulation of Human Colon Carcinoma 470
D. Byron McGregor, MD; Laura L. Morriss, PhD; Pacita B. Manalo, MD; Richard A. Bomberger, MD; Ronald S. Pardini, PhD, Reno, Nev
- Pentagastrin exerted a stimulatory effect that varied with the type of cell line of human colon cancer.

Inhibition of the Stimulated Canine Exocrine Pancreas by Amino Acids and Fat 473
Richard S. Stubbs, MB, ChB, MD, FRCS, FRACS, Wellington, New Zealand, Bruce E. Stabile, MD, San Diego, Calif
- Intravenous amino acids and intraduodenal lipid inhibited stimulated canine pancreatic secretion but probably by different mechanisms.

Detection of the Cancer-Prone Colon, Using Transepithelial Impedance Analysis 480
Richard J. Davies, MD; Renah Joseph; Horacio Asbun, MD; Marc Sedwitz, MD, San Diego, Calif
- Cancer-susceptible mice had a greater increase in electrical conductance after receiving a chemical carcinogen.

Recent Trends in the Management of Incisional Herniation 485
Raymond C. Read, MD, PhD, Gordon Yoder, PAC, Little Rock, Ark
- Recurrence rates after primary ventral hernia repair were 25% and 40% after a second ventral hernia repair.

Biochemical Adaptation of Venous Patches Placed in the Carotid Circulation 490
Dean M. Govostis, MD; Dennis F. Bandyk, MD; Thomas M. Bergamini, MD; Jonathan B. Towne, MD, Milwaukee, Wis
- Vein patch closure of arteries resulted in enhanced prostacyclin production compared with arteries closed primarily.

ORIGINAL ARTICLE

Limitations to Donating Adequate Autologous Blood Prior to Elective Orthopedic Surgery 494
Lawrence T. Goodnough, MD; J. Wasman; Kathleen Corlucci; Ann Chernosky, Cleveland, Ohio
- Autologous blood procurement was limited by low hematocrits and limited erythropoietic response to phlebotomy.

CLINICAL NOTE

Adenocarcinoma Arising in an Ileostomy: Report of Two Cases and Review of the Literature 497
Patricia L. Roberts, MD; Malcolm C. Veidenheimer, MD; Sharon Cassidy, RN, ET; Mark L. Silverman, MD, Burlington, Mass
- Adenocarcinoma occurred in ileostomy stomas in two patients many years after construction of the ileostomy.

BRIEF CLINICAL NOTE

Successful Reconstruction of Late Portal Vein Stenosis After Hepatic Transplantation 503
Velma P. Scantlebury, MD; Albert B. Zajko, MD; Carlos O. Esquivel, MD, PhD; Ignazio R. Marino, MD; Thomas E. Starzl, MD, PhD, Pittsburgh, Pa
- Portal vein stenosis occurred following liver transplantation in three young patients and was successfully corrected by operation.

TECHNIQUE

Cardiac Contusion: The Effect on Operative Management of the Patient With Trauma Injuries 506
Patrick Ross, Jr, MD, PhD; Linda Degutis, MSN; Christopher C. Baker, MD, New Haven, Conn
- Blunt trauma patients who have sustained a cardiac contusion can undergo elective operations with a low incidence of complications.

THE WRONG STUFF?

For patients with no gut function, TPN is the right choice. But feeding only parenterally can cause gut atrophy and lead to physiologic compromise.[1]

It has been estimated 80% to 85% of the patients traditionally placed on TPN can be managed by enteral methods alone.[2]

THE RIGHT STUFF

Because VIVONEX T.E.N. uses the gut, it protects the mucosal barrier and avoids intestinal atrophy that can lead to complications.[1] VIVONEX T.E.N. is clinically comparable to TPN,[3] plus it is the only leading enteral formula that contains the amino acid glutamine. And TPN doesn't contain glutamine, which animal studies have shown to be a key fuel for the small intestine[4] and to maintain the integrity of the intestinal villi and mucosal wall.[5,6]

VIVONEX® T.E.N.

BETTER THAN TPN BECAUSE IT KEEPS THE GUT WORKING

BECAUSE CONFIDENCE COUNTS...

In the successful treatment of venous disorders, both up-to-the-minute knowledge and the proper tools play significant roles. Also important is the confidence of knowing you're getting support for both from an industry leader. In the compression therapy industry, that means Camp International. Decades of experience have established Camp in the leadership position. That's because you can count on Camp for a full line of compression therapy products to meet most any need:

- **Camp graduated compression stockings** for therapy in cases of primary varicose veins, postphlebitic syndrome and other venous diseases. Readily available in sizes, styles and compressions to fit 90-95% of all patients.
- **LymphaPress® and Hemaflo 2® compression systems** for lymphedema, venous ulcers and deep vein thrombosis.

- **Seminars and Educational Programs** that support your efforts, including CME-accredited seminars, hospital in-service sessions, and extensive dealer training programs to ensure prompt and accurate filling of your prescriptions.
- **Patient Education Materials,** including a wide range of brochures to help you educate patients and encourage maximum compliance with your treatment program.

I WANT TO KNOW MORE ABOUT THE CAMP GRADUATED COMPRESSION STOCKING.

☐ Have a Camp representative call on me

☐ Send complete information ☐ Send a demonstration sample

MEDICAL STOCKINGS
CAMP®

CAMP MEDICAL STOCKINGS: Setting A New Standard Of Excellence.

Patient compliance is the key to successful compression therapy. Camp Medical Stockings provide a range of benefits to ensure patient compliance and effective, lasting treatment of venous disorders, so that your patients can continue to lead normal, active lives:

- **Physiologically correct pressures** from 20-30mm Hg. to 50-60mm Hg. and **extensive sizes and styles**—This permits accurate prescriptions for 90-95% of your patients.
- **Double-wrapped yarn**—Yarns in Camp Medical Stockings are double wrapped for improved comfort and greater durability. Unwrapped or single-wrapped yarn can produce bare spots when stockings are stretched. These bare spots cause patient discomfort as well as fraying of the material.
- **Low modulus, high elongation yarn**—Use of this yarn allows for greater elasticity with no loss of compression. This yarn, coupled with a knitting process which allows for more stitches per inch of fabric, results in easier application and greater patient comfort.
- **Electronic knitting process**—The knitting of each Camp Medical Stocking is electronically monitored to ensure consistency in both compression values and fit.
- **Cosmetically acceptable**—The aesthetically pleasing, neutral colors of Camp Medical Stockings encourage maximum patient compliance.

ETHICON* sutures must pass as many as 100 tests before they reach the O.R. to make sure they pass the most important one...YOURS!

ETHICON controls *every* step in the manufacturing process, from raw materials to finished product. And at every step, sutures are rigorously tested: over 100 times in the production of both PROLENE* polypropylene suture and Coated VICRYL* (polyglactin 910) suture. Quality assurance from beginning to end...it's typical of the extra effort we invest in every suture that carries the ETHICON name.

KAISER PERMANENTE

Good People. Good Medicine.

NORTH CAROLINA

Kaiser Permanente is seeking board certified/eligible general surgeons for our Raleigh and Charlotte Medical Offices. Excellent salary/benefits including malpractice, retirement and shareholder opportunity. C.V. to:

Phyllis Kline,
Recruitment Coordinator-ARS
Carolina Permanente
Medical Group, P.A.
3120 Highwoods Blvd.,
Raleigh, NC 27604

GENERAL SURGEON

Surgical group serving a small, rural community of approximately 25,000 is looking for a Board Certified or Board Eligible General Surgeon. Surgical staff now consists of 4 general surgeons, one of whom is anticipating retirement. Practice is located next door to a progressive 76-bed acute care hospital. Area is year-round outdoor resort with hunting, fishing, hiking, snow-skiing, water-skiing, and many other outdoor recreational activities. Located 120 miles southeast of Pittsburgh and 200 miles west of Baltimore. West Va. University Medical Center is located 60 miles to the west. Contact: C. William Fedde, M.D., Garrett Surgical Group, Suite 1, 311 N. 4th St., Oakland, Maryland 21550 (301) 334-8282.

GENERAL SURGEON

Board Certified or eligible with a special interest in trauma and critical care to join *200+* physician multi-specialty group. Large referral practice in Big 10 university town. Excellent guarantee with incentive package, liberal fringe benefits and early partnership. Contact:

Robert C. Parker, M.D.
Carle Clinic
Urbana, IL 61801
217-337-3223

PARTNERS PRACTICING GOOD MEDICINE.

Bring your outstanding surgical skills to the Southern California Permanente Medical Group and experience the freedom to focus on patient work. Not paperwork.

We are an HMO multispecialty group practice — a partnership composed of and managed by SCPMG physicians.

Opportunities exist for board eligible/certified **Surgeons** with a combined practice of Peripheral Vascular and General Surgery.

Consider the advantages: the finest equipment and latest technology; the availability of consultations with other physicians of distinction; and a broad network of exceptional support personnel backed by the resources of one of the nation's leading HMO's.

Our compensation is competitive and benefits are outstanding. They include: professional liability, medical and dental coverage, vacation and sick leave, continuing education, life insurance and retirement plans. **After two years full-time employment, physicians are eligible to be considered for partnership.**

For a physician application, please call (818) 405-3224 or send your curriculum vitae to: Physician Recruitment, Dept. 78E8, Walnut Center, Pasadena, CA 91188-8854.

Equal Opportunity Employer M/F/H

KAISER PERMANENTE

Good People. Good Medicine.

Chairman, Department of Surgery

The Mercy Hospital of Pittsburgh, a 500-bed advanced teaching and referral center, is currently searching for a Chairman, Department of Surgery. The Surgery department contains 11 divisions representing the major surgical specialties and sponsors a 25 position general surgery residency. Mercy is a Level I Trauma Center, a regional Burn Center, and a Cardiac Surgery Center and serves as a referral center for tertiary level neurosurgical and orthopedic care.

Interested candidates must be board certified in general surgery and have demonstrated clinical, teaching, and administrative expertise.

Submit curriculum vitae in confidence to:

Jeanne A. Cooper, M.D.
Chairman, Search Committee for
Surgery Chairman
Mercy Hospital of Pittsburgh
1400 Locust Street
Pittsburgh, PA 15219

Candidates will be reviewed monthly until the position is filled.

The Veterans Administration and Surgical Education in the United States

This issue of the *Archives of Surgery* contains reports presented at the 12th Annual Meeting of the Association of Veterans Administration (VA) Surgeons. Since its founding in 1930, the VA has played an increasingly important role in the American medical care system. The VA system of care developed slowly until the conclusion of World War II. There were 97 VA hospitals, mainly located in rural America, caring for patients with chronic medical problems. Following World War II, the rapid downsizing of a huge military medical system created a need for the VA to care for a large number of patients transferred from the military. The simultaneous reestablishment of full activity of the medical schools created a need for training sites and teachers. Over the next 45 years this affiliation was to become an excellent marriage.

President Harry S Truman appointed GEN Omar N. Bradley to head the VA. Paul R. Howley, MD, was named VA chief medical director, and Paul B. Magnusen, MD, chairman of the department of orthopedic surgery at the Northwestern University School of Medicine in Chicago, was selected as his aide. Dr Magnusen's concept of affiliations between the VA and medical schools was implemented promptly at the Hines VA Hospital in Chicago, where 56 residents (many medical veterans returning from the service) from Northwestern University and University of Illinois schools of medicine completed their training.[1] These affiliations were followed by similar agreements with medical schools in Minneapolis, Minn, Boston, Mass, New York, NY, and San Francisco, Calif. The number of medical centers in the VA system increased to 172 by the 1980s, of which 134 are affiliated with 102 medical schools.

The development and monitoring of these affiliations is the function of the dean's committee, chaired by the dean of the school of medicine and composed of top management of the VA medical center and the chairs of the departments utilizing the facility for medical student and resident physician training. The hospital provides the plant, equipment, personnel, patients, salary support, research space, and monies; the school helps to recruit faculty, staff, and residents. The VA is responsible for quality assurance and utilization review of patient care, and the school is responsible for the quality of the educational and research programs.

This metamorphosis of the VA and its marriage with the medical schools has not been without controversies. However, without this interdependent relationship, both would be very different organizations in terms of mission, quality of patient care, teaching, and research productivity.

Over 50% of all physicians practicing in the United States have received part of their education in VA medical centers. During fiscal year 1989-1990, the VA is supporting 8328.9 full-time resident positions (12.7% of the total resident positions in the United States). This includes 884 general surgery staff positions (11% of the US total) and 1072 residents in the surgical specialties (13.6% of the US total). Extensive VA-supported training also exists for medical students, nurses, dentists, pharmacists, psychologists, social workers, and a full complement of other medical providers and support personnel. During the 1987 academic year, there were 105 000 people from 1000 professional schools in training at VA medical centers.

Medical school affiliations caused the rapid growth of the research program in the VA system. This critical program affects the ability to successfully recruit and retain academic personnel. The total dollar allocation for research by the VA system exceeds $500 million per year, thus constituting a major component of American medical research.[2] The VA is also a major source of faculty salary support. Its patients present a spectrum of diseases essential to increasing the depth and scope of clinical experience needed to maintain a well-balanced training program.

American surgical education and research would change significantly if VA resources were not present. Furthermore, the flexibility offered medical schools by this relationship allows the schools a greater ability to change in this time of major funding challenges (ie, training programs and less financial support for research). The need for support of these two partners has never been more critical to their continued success.

Common Bile Duct Healing

Do Different Absorbable Sutures Affect Stricture Formation and Tensile Strength?

Kenneth W. Sharp, MD; Charles B. Ross, MD; Vicki N. Tillman; John F. Dunn, MD

• Few basic investigations have addressed the problem of common bile duct strictures. We systematically investigated the healing canine end-to-end choledochal anastomosis and tested the hypothesis that common bile duct anastomoses sutured with monofilament polyglyconate absorbable suture would heal with less stricture formation and greater tensile strength than those sutured with braided polyglactin 910 and chromic catgut sutures. Seventy-six canines, randomized to control vs sutured groups, underwent either mobilization (controls) or transection of the mid–common bile duct and were allowed to heal 5, 10, 15, or 50 days postoperatively before sacrifice. The type of absorbable suture used to construct a common bile duct anastomosis was found to have no major effect on anastomotic strictures nor on anastomotic breaking strength. Polyglyconate suture caused significantly less perianastomotic inflammation than did chromic suture, with polyglactin 910 sutures evoking an intermediate inflammatory response. Surgeons may safely choose sutures for biliary procedures based on the clinical circumstances and personal preference.

(*Arch Surg.* 1989;124:408-414)

Biliary strictures are a complex surgical problem with high recurrence rates, yet little basic research has focused on their pathogenesis.[1-4] A variety of methods for repair of common bile duct (CBD) injuries and strictures have been reported,[5-9] but many controversies still exist over anastomotic techniques, stenting, and the use of absorbable vs nonabsorbable sutures. Nonabsorbable sutures have fallen into disfavor because of erosion into the duct lumen where they have served as a nidus for the collection of biliary debris and stones.[10-12] A range of absorbable sutures are now available for use in biliary surgery, including the more recently introduced monofilament polyglyconate (PGN) suture (Maxon), which retains tensile strength longer while inciting less inflammation than chromic catgut and earlier synthetic absorbable sutures.[13] The monofilament configuration of this suture also offers the advantage of less drag and sawing when used in delicate, friable tissues. Although CBD stricture formation may depend on many factors, differences in suture composition, structure, degradation, and handling properties, as well as the tissue inflammatory response to the suture, may influence healing and stricture formation in the CBD.

We systematically investigated the biomechanical properties of the healing end-to-end canine CBD anastomosis in this study and tested the hypothesis that CBD anastomoses sutured with monofilament PGN would heal with less stricture formation and greater tensile strength than anastomoses sutured with chromic catgut (chromic) or braided polyglactin 910 (PGA-910) sutures.

MATERIALS AND METHODS

Design

Seventy-six adult mongrel dogs of both sexes (average weight, 29 kg) were randomly assigned to a healing period (5, 10, 15, or 50 days) and suture vs control groups, as shown in Table 1. Two dogs served as control animals for each healing period, and five additional dogs were studied at healing period 0 as controls not operated on.

Operative Procedure

Preoperatively, dogs were fasted for 24 hours with water allowed ad libitum. Dogs were anesthetized intravenously with sodium pentobarbital, 30 mg/kg, and were endotracheally intubated. A blood sample was taken for the determination of the serum total bilirubin and alkaline phosphatase levels. Dogs randomized to suture groups underwent laparotomy, cholecystectomy, and transection of the mid–CBD using minimal periductal dissection. End-to-end CBD anastomosis was next accomplished using interrupted, simple 5-0 sutures with atraumatic needles of equivalent sizes. Dogs randomized to control groups underwent laparotomy, cholecystectomy, and mobilization of the mid–CBD with minimal periductal dissection and without CBD transection. Postoperatively, dogs were allowed access to fresh water ad libitum. Regular chow was resumed on the second postoperative day. The protocol for the operative procedure and care of these animals was approved and monitored by the Nashville (Tenn) Veterans Administration

Accepted for publication December 16, 1988.

Presented as a poster exhibit at the 12th Annual Surgical Symposium of the Association of Veterans Administration Surgeons, Minneapolis, Minn, May 13-14, 1988.

Medical Center animal care committee under the guidelines of the American Association for the Accreditation of Laboratory Animal Care.

Sacrifice

A blood sample was taken for the determination of serum total bilirubin and alkaline phosphatase levels, following which the dogs were weighed and then sacrificed by intravenous barbiturate overdose. Laparotomy was performed and the peritoneal contents were inspected for gross or contained bile leaks, abscesses, and adhesions. The hepatic hilum, CBD, and duodenum were removed en bloc and submitted for study.

Cholangiography

A cannula was inserted into a proximal hepatic duct, and all other proximal ducts were ligated. The specimen was placed lying flat directly on the film cassette to minimize magnification. A cholangiogram was taken after the distal CBD was occluded, and contrast medium was injected into the CBD via the cannula to a pressure of 25 cm contrast, as measured manometrically.

The CBD width was measured at the anastomosis (Fig 1) and the area of mobilization in controls, as well as 1.5 cm proximal and 1.5 cm distal to the anastomosis. A dilatation ratio (proximal width to distal width) was derived as an indication of proximal duct dilatation or functional obstruction. A stricture ratio (anastomotic width to distal width) was derived as an indication of the true anastomotic stricture relative to a normal duct. In controls not operated on, ie, day 0, the smallest portion of the mid–CBD was considered the area of mobilization.

Tensiometry

Standard specimen strips 3 mm wide and 4 cm long were prepared and vertically mounted in a tensiometer (Model 1130, Instron Inc, Canton, Mass) with an electronic load-weighing system synchronously linked to a strip-chart recorder. The distance between the edges of the clamps was set at 1 cm. A distracting force was constantly applied at 5 cm/min and charted as load vs time. Breaking strength was determined as the maximal load required to pull the strip specimen apart and was reported as grams per millimeter of strip width. Strips were cut for tensiometric analysis so that sutures were excluded or the sutures were cut or removed.

Histologic Grading

Standard specimens were fixed in Bouin's solution and stained with hematoxylin-eosin. Perianastomotic inflammation was qualitatively assessed by an investigator who had no knowledge of sutures and healing periods. A grading scale from 1 to 4 was employed. Grade 1 represented no discernible inflammation, grade 2 represented minimal inflammatory cellular infiltration mainly confined to an area 500 μm to either side of the anastomosis, grade 3 inflammation represented a heavier infiltrate confined to an area 1000 μm to either side of the anastomosis, and grade 4 inflammation was most severe with a diffuse and heavy cellular infiltrate spreading greater than 1000 μm from either side of the anastomosis.

Statistical Analysis

Mean values and SEMs were calculated for all variables. Main effects due to healing periods and types of suture on the dilatation ratio, stricture ratio, breaking strength, and inflammatory grade were evaluated by a 4×4 ANOVA, with $P<.05$ considered significant. Multiple comparisons between groups at individual healing periods and within groups over time were made using the Student Neuman-Keuls Test (NK), with $P<.05$ considered significant.[14] The Student t test for independent samples was likewise used where appropriate, with P adjusted as necessary to correct for the multiple use of single data groups for comparison.[14] Pearson's correlations were used to evaluate the relationship between inflammation and anastomotic stricture ratio and breaking strength, with $P<.05$ considered significant.

RESULTS

Seventy-six dogs were required to complete the study. Three dogs developed free anastomotic leaks within the first 2 weeks postoperatively (two sutured with PGA-910 and one with chromic sutures) and were excluded from further analysis. These technical failures all occurred early in the course of the study. All other animals tolerated their operative procedures well with no statistically significant differences in postoperative weight changes between sutured vs control animals. Serum alkaline phosphatase levels were more frequently elevated (>80 U/L) in animals sacrificed within 15 days of operation and decreased with time. Total bilirubin levels followed the same trend, but none of the control animals had elevated total bilirubin levels (> 9 μmol/L). Laboratory results are summarized in Table 2.

Table 1.—Experimental Design*

Healing Period, d	Controls	Suture Type		
		Chromic	PGA-910	PGN
0 (not operated on)	5	0	0	0
5	2	5	5	5
10	2	5	5	5
15	2	5	5	5
50	2	5	5	5

*Values represent the total number of animals in each group. PGA-910 indicates polyglactin 910; PGN, polyglyconate.

Cholangiographic analysis revealed the presence of proximal ductal dilatation (proximal width to distal width ratio, >1.0) in all suture groups and control groups not operated on at all healing periods (Table 3). Proximal ducts of animals sacrificed earlier tended to be more dilated than those of animals allowed to heal for 50 days and sacrificed later, but overall, no statistically significant effects were attributable to treatment, ie, control and suture types ($P=.296$), or to the healing period ($P=.211$). Visual inspection of the data revealed minor differences within suture groups, with chromic-sutured bile ducts substantially more dilated at 10 days compared with those allowed to heal 50 days.

Cholangiographic analysis of the stricture ratio was done to assess true narrowing at the anastomosis compared with a normal duct. No statistically significant main effect was found due to treatment, ie, control vs suture type ($P=.701$), but these results were affected by the healing period ($P<.001$) (Table 4). Overall, strictures were significantly more severe at 5 days compared with those present at 15 days (NK, $P<.05$). Ten-day animals gave intermediate results with no significant differences between their stricture ratios and those of either the 5- or 15-day groups. Strictures at day 50 were significantly less severe than the strictures at all other healing periods (NK, $P<.05$ for all comparisons).

Visual inspection of the data for stricture ratios suggested the presence of minor differences within groups even though the 4×4 ANOVA showed no overall suture effects, so the NK was used to compare stricture ratios present at different healing periods within each suture group (Table 5). Fifty-day chromic CBD anastomoses were significantly less strictured than the 5-day chromic group (NK, $P<.05$) but no different compared with 10- or 15-day chromic groups. No major differences were present between the stricture ratios at any of the healing periods in the PGA-910–sutured animals. The PGN-sutured dogs, however, had significantly less CBD anastomotic stricture at 50 days compared with 5, 10, or 15 days (NK, $P<.05$ for all comparisons). The CBD anastomoses sutured with PGN

Fig 1.—Examples of specimen cholangiograms. A indicates the anastomosis. Left, A 15-day polyglactin 910–sutured anastomosis. Right, A 50-day polyglactin 910–sutured anastomosis.

also were significantly less strictured at 50 days compared with PGA-910–sutured 50-day anastomoses.

Analysis of CBD anastomotic breaking strength data revealed a significant effect due to treatment, ie, control vs sutured bile ducts ($P<.001$). This effect was observed because the breaking strength of intact CBD strips (controls) was significantly greater than the breaking strengths of sutured anastomoses (NK, $P<.05$ for all comparisons) at all of the healing periods tested. However, no significant differences emerged between the types of suture used to construct CBD anastomoses (Table 6).

Overall, CBD anastomotic breaking strength also was significantly affected by the healing period ($P<.001$), with breaking strength rising with longer healing times, as one would expect (Table 4). The CBD anastomotic breaking strength was significantly weaker in animals allowed to heal for 5 days compared with all other healing periods (NK, $P<.05$). The CBD anastomotic breaking strength was greatest in 50-day animals compared with all earlier healing period groups (NK, $P<.05$ for all comparisons).

A more detailed inspection of the breaking strength data revealed slightly different patterns of healing depending on the particular type of suture (Table 6). The CBD anastomoses sutured with chromic had no significant differences in breaking strength at 5, 10, or 15 days. For chromic-sutured animals, however, statistically significant increased breaking strength only was present when comparing the 50-day group with either the 5-, 10-, or 15-day groups (NK, $P<.05$ for all comparisons). The CBD anastomoses sutured with PGA-910 were significantly stronger at 15 days compared with 5 days (NK, $P<.05$), had intermediate strength at 10 days, and had significantly greater strength at 50 days compared with the 5- and 10-day but not the 15-day PGA-910–sutured groups (NK,

Table 3.—Dilatation Ratios (Proximal Width to Distal Width) for Healing Periods and Suture Groups*

Healing Period, d	Control	Suture Type: Chromic	Suture Type: PGA-910	Suture Type: PGN
5	1.59±0.42	2.11±0.40	2.05±0.77	1.49±0.27
10	1.51±0.07	2.46±0.55†	1.66±0.21	1.55±0.19
15	1.16±0.02	1.63±0.23	1.83±0.18	1.35±0.10
50	1.02±0.02	1.17±0.20	1.32±0.11	1.98±0.19

*Values represent mean±SE for that group. Dilatation ratio greater than 1.0 represents proximal dilatation. PGA-910 indicates polyglactin 910; PGN, polyglyconate.

†Number is significantly different from the dilatation ratio of 50-day chromic animals ($P<.05$ by Neuman-Keuls Test).

$P<.05$ for 50-day vs 5- and 10-day comparisons). Anastomoses sutured with PGN were significantly stronger at 50 days compared with 5 days (NK, $P<.05$), but intermediate CBD anastomotic breaking strengths were present at 10 and 15 days, not significantly different from either the 5- or 50-day groups.

To develop a broader understanding of CBD healing in terms of anastomotic breaking strength as it relates to the breaking strength of undisrupted bile duct, sutured animals in each healing period were combined into single groups and compared with the day 0 control group not operated on. Student's t test was used, with $P<.0125$ considered significant to correct for multiple uses of the single set of control data from animals not operated on.[14] The CBD breaking strength in these controls was 515.4±38.4 g/mm compared with 221.6±18.8 g/mm in animals allowed to heal for 50 days. Hence, CBD anastomotic breaking strength in sutured animals never returned to control levels during the course of this study, only regaining 43% of the strength of intact tissue by 50 days.

Perianastomotic inflammation was qualitatively graded based on both the degree of inflammatory cellular infiltrate present and the area around the anastomosis where the infiltrate was a predominant finding. Inflammatory changes were most severe in the animals sacrificed earlier, but particularly at 5 days, the inflammatory response in chromic anastomoses seemed most severe (Fig 2). Mononuclear cells and macrophages were the dominant inflammatory cells present in all groups at all healing periods but neutrophils were seen frequently in animals sacrificed earlier. Chromic sutures tended to evoke a greater inflammatory foreign-body reaction than either PGA-910 or PGN. The foreign-body response to both PGA-910 and PGN was minimal.

Table 4.—Effect of Healing Period on Common Bile Duct Anastomotic Strictures and Breaking Strength*

Healing Period, d	Stricture Ratio (Anastomotic Width to Distal Width)	Breaking Strength, g/mm

*Values represent mean±SE for that group. PGA-910 indicates polyglactin 910; PGN, polyglyconate.

†Value is significantly different from the 5-day polyglactin 910 group.

‡Value is significantly different from the 5-, 10-, and 15-day chromic groups.

§Value is significantly different from the 5- and 10-day polyglactin 910 groups.

‖Value is significantly different from the 5-day polyglyconate group (comparisons by the Neuman-Keuls Test, $P<.05$ is significant).

The overall perianastomotic inflammatory response was evaluated by 4 × 4 ANOVA. In general, all groups, including the controls, showed more inflammation in the earlier healing periods, with inflammation decreasing as the healing time increased (Table 7). Significant effects were due to treatment, ie, control and suture type ($P<.001$), as well as to the healing period ($P=.005$). Animals sutured with chromic had significantly greater perianastomotic inflammation than either control animals or those sutured with PGN (NK, $P<.05$ for both comparisons). Animals sutured with PGA-910 had an intermediate result, tending to have less inflammation than chromic, yet more than PGN, but not statistically different from either the chromic or PGN group. Fifty-day anastomoses were significantly less inflamed overall than either the 5-, 10-, or 15-day groups (NK, $P<.05$ for all comparisons).

Table 7.—Perianastomotic Inflammation for Healing Periods and Suture Groups*

		Suture Type		
Healing Period, d	Control	Chromic	PGA-910	PGN
5	2.0 ± 0	3.60 ± 0.25	2.75 ± 0.25	2.0 ± 0
10	2.50 ± 1.5	3.0 ± 0.32	2.20 ± 0.20	2.0 ± 0.32
15	1.0 ± 0	2.75 ± 0.48	3.0 ± 0.32	2.40 ± 0.51
50	1.0 ± 0	2.20 ± 0.20	2.0 ± 0.32	1.60 ± 0.25

*Values represent mean ± SE for that group. Grade 1 indicates no discernible inflammation, whereas grade 4 indicates maximal inflammatory response. Overall, the inflammatory response incited by chromic suture tends to be greater than that incited by polyglactin 910 (PGA-910) suture (Neuman-Keuls Test, $P<.10$) and is significantly greater than the inflammatory reaction to polyglyconate (PGN) suture (Neuman-Keuls Test, $P<.05$). Overall, inflammation at 50 days is significantly less than that present at either 5, 10, or 15 days (Neuman-Keuls Test, $P<.05$ for all comparisons).

There was a weak negative correlation between inflammation and anastomotic stricture ratio ($r=-.26$, $P=.02$; more inflamed anastomoses tended to have tighter strictures). The correlation between inflammation and anastomotic breaking strength was weakly positive ($r=.29$, $P=.007$; anastomoses with greater degrees of inflammation tended to have greater strength).

COMMENT

The pathogenesis of biliary strictures represents an important fundamental problem in general surgery. It is surprising that more basic investigation of bile duct healing has not been done since virtually hundreds of articles have

Fig 2.—Perianastomotic inflammation and tissue reaction to sutures in 5-day common bile duct anastomoses. Top left, A polyglactin 910–sutured anastomosis. A mild inflammatory reaction, grade 2, is present. Top right, A chromic-sutured anastomosis demonstrating a more intense, grade 4, inflammatory response. Bottom left, A polyglyconate suture eliciting a minimal foreign-body reaction. Bottom right, A vigorous inflammatory response to chromic suture at 5 days. been published on intestinal anastomotic healing and anastomotic techniques. No standard method for the repair of CBD injuries and strictures exists. Individual surgeons and institutions favor techniques that yield good results in their practices, yet no technique has uniformly produced results so superior to others that it makes them obsolete. The issues of whether to stent and for how long, whether to do an end-to-end choledochal or some type of biliary-enteric diversion, and what type of sutures to use are controversial. Perhaps least controversial at this time is the general acceptance that absorbable sutures are preferable to nonabsorbable ones, because of the tendency of the latter to erode into the duct lumen, where they may cause recurrent episodes of obstructive jaundice and cholangitis.[10-12] Differences in the type of absorbable sutures available and their relative evaluation in biliary surgery have been minimally addressed.[15]

This study was done to address the main question of whether the type of absorbable suture used to construct an end-to-end choledochal anastomosis makes any difference in terms of CBD anastomotic stricture formation and tensile strength, as well as to add more basic information about wound healing in the bile duct. Absorbable sutures available for surgical use are continually changing, with newer sutures being used that are ideally designed to maintain tensile strength during the early phases of wound healing, while simultaneously eliciting minimal foreign-body inflammatory reaction. Catgut suture elicits a strong foreign-body inflammatory response in tissue. Degradation of chromic catgut is by enzymatic proteolysis, and, when exposed to bile, it loses 60% of its initial tensile strength after 7 days.[15] The PGA-910 suture is a braided synthetic one, consisting of a copolymer of glycolic and lactic acids present in a ratio of 90:10, which is slowly hydrolyzed by water and elicits less inflammation than catgut.[16] This suture loses 40% to 50% of its initial tensile strength by 7 days when immersed in bile.[15] The PGA-910 suture represents the first generation of synthetic absorbable sutures available for widespread clinical use. This suture handles much like silk because of its braided construction, and it is pliable and easy to tie with knots that go down smoothly and lie flat. However, also because of its braided construction, this type of suture has a high degree of drag when being pulled through tissues and tends to saw delicate, friable tissues, a particular disadvantage when suturing bile ducts.

The latest generation of absorbable suture is composed of a synthetic polymer of polyglyconate, which consists of glycolic acid and trimethylene carbonate combined in a 2:1 ratio.[13] This monofilament suture is more slowly degraded and absorbed and retains its tensile strengths in tissue longer than the first-generation absorbables.[13] It also evokes minimal foreign-body inflammatory reaction and is slowly absorbed by nonenzymatic hydrolysis. This suture offers the quality of less tissue drag and sawing than earlier synthetic absorbable sutures. Because tissue inflammation has been reported to be less around suture materials with low capillarity (monofilaments compared with braided sutures), available evidence suggests that the tissue inflammatory response to this newer synthetic absorbable suture would be less than that elicited by braided ones.[17]

The relationship of tensile strength and tissue inflammation to function, integrity, and subsequent stricture formation of an anastomosis is incompletely understood. It seems reasonable to assume that increased tissue inflammation due to an inflammatory suture, compared with a suture that elicits a minimal inflammatory response, would result in increased stricture formation. It also is tempting to speculate that increased inflammation would lead to greater scar formation with increased tensile strength, but this is also unknown. Hence, we included an evaluation of perianastomotic inflammation associated with different sutures in this study to see if inflammation would have a major effect on the clinically important variables of anastomotic stricture and tensile strength. Although the correlations were weak, there was a notable negative relationship between perianastomotic inflammation and the anastomotic stricture ratio, which indicated that more inflamed anastomoses also tended to have tighter strictures. Likewise, there was a substantial positive relationship between anastomotic breaking strength and perianastomotic inflammation, with more severely inflamed anastomoses having greater anastomotic breaking strength. These relationships provide evidence that favorably supports the use of a suture that inherently maintains tensile strength longer, yet elicits a minimal inflammatory response for procedures involving the CBD.

Our cholangiographic data showed generally expected results—that animals sacrificed earlier showed edematous anastomoses with dilated proximal ducts, and that this improved with time. The relationships between inflammation and stricture and inflammation and breaking strength were not as clear when the data for individual suture groups were evaluated by ANOVA. The more inflammatory suture did not greatly increase stricture formation, but there was a trend toward less-strictured anastomoses in 50-day PGN-sutured animals. Our data on tensile strength also failed to show differences in anastomotic breaking strength between the suture groups. Thus, the function and integrity of choledochal anastomoses appeared to be influenced by factors other than or in addition to those assessed in this study.

The CBD anastomotic breaking strength never returned to that of intact tissues, even after 50 days of healing. This finding conflicts with that of Northover and associates,[1] who reported that the breaking strength of pig end-to-end CBD anastomoses returned to normal values by 15 days and greatly exceeded the strength of intact CBD tissue at 50 days. This difference may be due to species variation, especially since it relates to the blood supply of the bile ducts in these animals. Our finding that the CBD anastomosis has not reached even half of the strength of intact CBD tissues by 50 days of healing also may reflect a basic difference between healing of the bile duct and that of other tissues, such as stomach or colon, which reach approximately 70% of strength of normal tissues by 21 days.[16,18,19] Earlier studies implicated bile as the cause of impaired healing in the CBD compared with the stomach or intestine.[20] In the study by Douglass and associates,[20] canine CBD anastomoses healed with less stricture formation when bile was completely diverted away from the healing CBD anastomosis. However, the biomechanical properties of these anastomoses were not assessed in their study, so the role of bile as a mediator of altered CBD healing and stricture formation remains speculative.

Perianastomotic inflammation was significantly affected by both the type of absorbable suture used to construct a CBD anastomosis and the duration of healing. We found that inflammation decreased with time, and that PGN suture evoked much less perianastomotic inflammation than chromic suture and tended to cause less than PGA-910 suture. We believe that the increased inflammation present in PGA-910–sutured anastomoses was likely due to the increased capillarity of the braided suture, which may have allowed more bile to seep into the tissue than may have occurred around a monofilament suture. It

might have been useful to assay collagen synthesis to determine if there was a correlation between increased collagen synthesis and increased inflammation as a potential mediator of stricture formation, but previous work by Casey and Peacock[4] suggested that wound contraction, not collagen synthesis, is the fundamental biological process leading to stricture of a repaired CBD.

Experience gained from the present study has reemphasized the critical importance of the standard surgical principles of gentle tissue handling, maintenance of blood supply, precise hemostasis, and the creation of a tensionless anastomosis when operating on the CBD. Ultimately, suture choice depends on the surgeon's confidence in the suture as well as its appropriateness for a given clinical situation. The surgeon's confidence in a suture clearly is affected by its tendency to drag or saw through tissue, the security of knots tied, the number of knots needed for security, and overall ease of "handling." Our data support the use of any of the three sutures in this study based on no functional anastomotic differences in short-term analysis, but our preference remains for a monofilament suture that does not cut through inflamed tissues, yet ties easily and securely. A monofilament suture is generally preferable in situations demanding low tissue drag (eg, when suturing inflamed or edematous ducts) but is not as easily handled or tied as PGA-910.

In conclusion, our results demonstrate that the type of absorbable suture used to construct an end-to-end choledochal anastomosis does not affect the formation of CBD anastomotic strictures or tensile strength. A PGN suture causes substantially less perianastomotic inflammation than chromic suture and tends to cause less than PGA-910 suture, but a clinical advantage to this property in terms of CBD anastomotic stricture or tensile strength was not apparent in this short-term study. Further basic investigations clearly are needed to study the effects of biliary stents on CBD healing, to study the effects of alterations in blood supply on the healing CBD anastomosis, to clarify the effect of bile on CBD healing, and to characterize the healing biliary-enteric anastomosis.

This work was supported by the National Institutes of Health (Bethesda, Md) grant BRSG RR 05424 24-40, and a grant provided by the American Cyanamid Company, Wayne, NJ. The study was conducted at the Nashville (Tenn) Veterans Administration Medical Center research facility, and the support and assistance rendered to us by the research staff there is appreciated. We wish to thank Lillian Nanney, PhD, and Mary McKissock for technical support in the histologic preparation of our specimens. Cheri Premeau, MA, of Statistical Research Consultants Inc, Nashville, Tenn, provided statistical consultation and support.

Changing Concepts in Surgical Management of Renovascular Hypertension

John A. Libertino, MD; Thierry A. Flam, MD; Leonard N. Zinman, MD; Christopher Y. Ying, MD; Donald J. Breslin, MD; Neil W. Swinton, Jr, MD; M. D. Phelps, Jr, MD; Nicholas P. Tsapatsaris, MD; Bartholomew O'B. Woods, MD

As newer surgical techniques and concepts have emerged, including revascularization of the totally occluded renal artery and alternatives to aortorenal bypass (hepatic, splenic, or iliac artery to renal artery grafts), our patient population has changed. Patients with diffuse atherosclerotic disease, bilateral renal artery stenosis, totally occluded renal arteries, and azotemia are being referred for renal revascularization, thereby changing the indications for operation and the results that can be anticipated. Although our results in patients operated on solely for uncontrollable hypertension or renal failure have been successful, much work needs to be done to improve the results obtained when patients have a combination of uncontrollable hypertension and renal failure (*Arch Intern Med* 1988;148:357-359).

Epidural Anesthesia in Patients Undergoing Thoracic Surgery

Barbara K. Temeck, MD; Paul W. Schafer, MD; Woo Y. Park, MD; John W. Harmon, MD

• Epidural anesthesia has been reported to exert beneficial effects in surgical procedures. Over the past 3 years at the Veterans Administration Medical Center in Washington, DC, thoracic surgical procedures have been done using a combined technique of epidural anesthesia with light general anesthesia. A retrospective review of this experience from January 1984 to November 1987 was done in 90 consecutive patients. Postoperative extubation of patients was accomplished immediately in 32%, within 1 hour in 34%, within 3 hours in 28%, within 18 hours in 4%, and was prolonged in only 1% of patients. Mortality was 2% and morbidity was 3%. This analysis indicates that the technique of epidural anesthesia with light general anesthesia provided satisfactory anesthesia with low mortality and morbidity in a high-risk group of patients undergoing surgery.

(*Arch Surg.* 1989;124:415-418)

Epidural anesthesia has been used successfully for lower abdominal, peripheral vascular, and major orthopedic procedures.[1-3] Potential advantages of the epidural anesthesia technique in these procedures include a reduction in cardiac preload and afterload,[4] higher postoperative pulmonary flow rates with improved oxygenation,[5,6] decreased incidence of venous thromboembolism[7] as well as blood loss,[8,9] better suppression of stress responses,[10] and a positive effect on postoperative nitrogen balance.[11] Potential disadvantages include the time required to establish the epidural anesthesia, volume needed to avoid decrease in blood pressure, and potential for technical complications such as epidural hematoma. Questions can be raised as to what the overall influence would be of the block on respiration, ie, inhibition or facilitation. Although postoperative pain relief could improve pulmonary function, the high level of epidural block could paralyze some of the ventilatory muscles; also, fluid requirements to maintain blood pressure might predispose to later congestive heart failure.

Epidural anesthesia alone was successfully used for thoracic surgical procedures on awake spontaneously breathing patients by Crawford et al.[12] However, the usual approach in the United States is to perform general thoracic surgery under general anesthesia with endotracheal ventilatory support. Advantages of general anesthesia are ease of administration, satisfactory relaxation, ability to control the depth of anesthesia, and good hemodynamic stability, which, however, can be affected by cardiorespiratory depressant effects of some agents. The disadvantage is a central depressant of respiration that can extend into the postoperative period in a patient who can awaken in pain and require longer postoperative intubation.

A combination of epidural anesthesia with light general anesthesia might offer a method of anesthesia that would maximize the benefits of each form of anesthesia. The purpose of this study was to examine the outcome of this technique for a group of patients operated on over the past 3 years at the Veterans Administration Medical Center in Washington, DC.

PATIENTS, MATERIALS, AND METHODS

Ninety consecutive patients underwent thoracic surgical procedures while receiving epidural anesthesia with light general anesthesia from January 1984 to November 1987. This retrospective study examines several categories of information concerning these patients.

For each patient the following factors were examined: age, sex, disease category (benign or malignant), stage and histologic features of malignant disease, and operative procedures with a risk assessment evaluation using the American Association of Anesthesiology (ASA) classification[13] and the analysis of Goldman et al.[14] The pulmonary status was examined by history and physical examination, chest roentgenogram, and data, when available, from pulmonary function tests.

Perioperative and Operative Data

No patient had a contraindication to the epidural anesthesia. In each patient, a No. 17 Tuohy needle was inserted into one of the lower thoracic intravertebral spaces. The epidural space was identified and with the bevel of the needle cephalad, a test dose of 3 mL of 0.5% bupivacaine hydrochloride with epinephrine (1:200 000) was injected followed after 2 minutes by the main dose of local anesthetic solution (10 to 12 mL) given at the rate of 0.7 mL/s. An epidural catheter was then inserted and fixed. The

analgesia level achieved was usually from T2-4 to S1-3. After confirming adequacy of the epidural anesthesia for the surgery, anesthesia was induced with thiopental (Pentothal) sodium, succinylcholine, or pancuronium bromide and a Robert Shaw or Carlens endobronchial tube was inserted. Anesthesia was maintained using a low concentration (0.25% to 0.5%) of either enflurane or isoflurane, nitrous oxide (50%), fentanyl citrate, and pancuronium. All patients received 100% oxygen during one lung ventilation. At the end of the surgical procedure, all patients received 1 to 2.5 mg of neostigmine (Prostigmine) bromide and 0.4 to 1.2 mg of atropine sulfate for reversal of neuromuscular blockage. During the operative procedure, monitoring of hemodynamic status included mean arterial blood pressure, central venous pressure, and mean blood loss. Postoperative assessment included recording the time at which each patient was extubated and the mean time elapsing prior to the administration of the first postoperative analgesic.

Clinical Outcome

Major clinical outcome was analyzed with regard to several variables. The first was mortality and morbidity. Mortality was defined as a death within 30 days of the operative procedure; morbidity was defined as cardiovascular problems such as myocardial infarction, ischemia, congestive heart failure, or arrhythmias. Respiratory problems were defined by the need for mechanical ventilation for more than 24 hours postoperatively or by the decision to reintubate a patient. Also considered were infections, such as development of pneumonia or wound infection, and renal, gastrointestinal, and neurological problems developing in the 30-day postoperative period.

RESULTS

There were 89 men and 1 woman with an age range from 32 to 80 years (median, 61 years). Twelve patients (13.3%) had benign disease with 2 excisions of bullae, one lobectomy, and 9 wedge resections. Table 1 outlines the treatment, stage of disease, and type of surgical procedures for the 78 patients with malignant disease (83% were epidermoid and the remainder were adenocarcinoma) as evaluated by the TNM staging system.[15]

The overall risk assessment of the patients indicated a mean ASA classification of II with 7 class I, 61 class II, 18 class III, and 4 class IV patients. The cardiac risk assessment of the patients by the index of Goldman et al[14] was 9.77 (SD = 3.53), which is the Goldman class II. The pulmonary risk factors are presented below.

Pulmonary Risk Factors	% (Proportion)
History of cigarette smoking (average, 60 pack-years)	97 (87/90)
Preoperative history of chronic obstructive pulmonary disease	69 (62/90)
Preoperative purulent productive cough	6 (5/90)
Forced expiratory volume in 1 s (FEV_1) less than 2 L	68 (45/66)
Maximal ventilatory volume less than 50% predicted	55 (36/66)

Seventy-three percent of the patients had pulmonary function tests with mean spirometric values of FEV_1 of 1.83 L (SD = 0.33), a forced vital capacity (FVC) of 2.97 L (SD = 0.57), an FEV_1/FVC ratio of 62% predicted, and a mean maximal ventilatory volume of 48% predicted.

Perioperative Data

No patient required more than light general anesthesia as a supplement to the epidural anesthesia. Stable hemodynamics as followed by continuous intra-arterial and central venous monitoring were maintained without vasopressors or afterload reducers except for one patient who required administration of one dose of ephedrine (5 mg) intravenously. The mean arterial pressure was 87 mm Hg with a normal range being 80 to 90 mm Hg; the average amount of fluid administered was 2800 mL, including blood products of which 1200 mL was given during the first hour of fluid administration. The mean duration of the operation was 4 hours. The following outlines the time period to accomplish extubation.

Time to Extubation	No. (%) of Cases
Immediate	29 (32)
1 hour	31 (34)
3 hours	25 (28)
18 hours (morning after)	4 (4)
>24 hours	1 (1)

First postoperative analgesia was given at 6.7 hours; thus, the mean duration of epidural analgesia was 10.7 hours. None of the patients required diuresis for pulmonary edema. The epidural catheter was removed on the first postoperative day.

Clinical Outcome

The mortality for the group of patients was 2.2% (2/90) due to myocardial infarction occurring on postoperative days 3 and 4. Morbidity developed in 3 (3.3%) of the 90 patients, including the 48-hour requirement for mechanical ventilation in 1 patient and pneumonia in 2 other patients. No adverse effects relating to epidural anesthesia resulted other than the previously described use of one dose of ephedrine for 1 patient.

COMMENT

This review was carried out to assess the results of epidural anesthesia with light general anesthesia for thoracic surgical procedures. The study indicates that the technique described provided effective and safe intraop-

*According to the point system of Goldman et al.[14]

erative anesthesia and early postoperative analgesia in these patients. Cardiovascular stability was maintained without a requirement for excessive fluid administration. The time to extubation was not prolonged. Mortality and morbidity were better than predicted by the ASA classification[13] and criteria of Goldman et al.[14] We suggest that to maximize the potential surgical benefits of this technique for other patients, careful preoperative risk assessment be emphasized to anticipate potential complications with the goal of preoperative preparation, such as volume correction, to prevent the complications. With regard to the anesthetic technique, it is recommended that the epidural anesthetic be given at the dermatome level where the operation is performed as at T7-8 for a sixth intercostal space incision to avoid hypotension that can occur at high levels of thoracic epidural anesthesia. Titration of the amount of local anesthetic should be done to avoid total sympathetic blockade. There should be slow induction of general anesthesia and the anesthesia should be maintained lightly just to allow toleration of the endotracheal tube with the anesthesia for the intraoperative and postoperative period provided by the epidural anesthesia.

In the series of patients under investigation, the patients were demonstrated to be at high risk for postoperative complications as defined by their pulmonary and cardiac risk factors. Postoperative pulmonary complications have been identified with the following risk factors[16] (the percentages or data in parentheses relate each factor to the patients in the study group): thoracic, upper abdominal surgery (100% of operations); preoperative chronic obstructive pulmonary disease (69% of patients); preoperative purulent cough (6% of patients); anesthesia time exceeding 3 hours (mean operative time 4 hours); cigarette smoking (87% of patients, average 60 pack-years); and age greater than 60 years (median age, 61 years).

Hodgkin[17] proposed the spirometric values listed below as indicating risk of postoperative pulmonary complications. The patients in this series were at high risk according to these criteria: (1) FEV_1 less than 2.0 L or 50% of predicted; (2) FVC_1 less than 50% of predicted; (3) FEV_1/FVC_1 less than 50% of predicted; (4) FEV_1 less than 1.0 L; (5) FVC less than 1.5 L; (6) FEV_1/FVC less than 35% of predicted; and (7) maximal ventilatory volume less than 50% of predicted.

The fact that there was no mortality and only 3.3% morbidity related to pulmonary problems is remarkable considering the pulmonary risk factors in the series reported herein. The surgical risk of the patients was also high as a result of their cardiac status.[16,18] The following ASA classification of physical status is the best available predictor of overall mortality from cardiac and noncardiac causes and is a fair predictor of cardiac deaths: I, a normal healthy patient for elective operation; II, a patient with mild systemic disease; III, a patient with severe systemic disease that limits activity but is not incapacitating; IV, a patient with incapacitating systemic disease that is a constant threat to life; and V, a moribund patient not expected to survive 24 hours with or without operation.

The patients in ASA class II have a predicted mortality of 1.3% for elective risk procedures, 1.7% for elective medium-risk procedures, and 5.4% for elective high-risk procedures.[13] However, computation of the cardiac risk index as described by Goldman et al[14] is more accurate in assessing the risk of cardiac death in patients undergoing surgery. Goldman identified nine independent factors that correlate with significant life-threatening and fatal complications in noncardiac surgical procedures:

Criteria	Points
History of myocardial infarction within 6 months	10
Age over 60 years	5
Physical examination	
S_3 or jugular venous distention	11
Important aortic stenosis	3
Electrocardiogram	
Rhythm other than sinus or sinus plus atrial premature beats on last preoperative electrocardiogram	7
More than five premature ventricular contractions per minute at any time preoperatively	7
Poor general medical status	3
Intraperitoneal, intrathoracic, or aortic surgery	3
Emergency operation	4
Total	**53**

Each factor was assigned a specific number of points. Patients could be separated into four classes of significantly different risk according to the point system of Goldman et al[14] (Table 2).

For the group of patients in this series, the 2.2% mortality corresponded to the cardiac risk index (class II) of Goldman et al.[14] However, the predicted cardiac morbidity of 5% did not occur.

The satisfactory outcome for the patients in this series despite their severe risk factors was probably influenced by several different factors. The level of central depression under the combined technique is slight as compared with that of general anesthesia alone so that breathing can be considered tranquil, which means similar to that of normal physiological sleep. The ventilation achieved is the "controlled respiration" described by Guedel and Treweek[19] in which maintenance of a careful degree of hypocapnia suppresses spontaneous respiration that can return as soon as the carbon dioxide level is allowed to become normal. Another explanation for the satisfactory pulmonary outcome of these patients is the influence of this technique on postoperative pulmonary function. General anesthesia with muscle relaxants does not relieve the depressant effects of early postoperative pain. Vital capacity and lung compliance fall, leading to the accumulation of bronchial secretions.[20] Under epidural analgesia with light general anesthesia, static compliance has been shown to decrease less.[21] There is enhancement of postoperative pulmonary function.[22]

With regard to the reduced incidence of cardiovascular complications, studies have shown a decrease in the size of the myocardial infarctions due to improvement in regional endocardial perfusion to the ischemic site by epidural analgesia as compared with general anesthesia.[4] Mechanisms thought to be involved are afferent sensory blockage, decreased adrenergic tone, and coronary and systemic vasodilatation with a decrease in cardiac preload and afterload.[23] The metabolic stability afforded by epidural analgesia may also blunt the surgical stress response with the stoppage of nociceptive spinal excitability and the inhibition of release of catecholamines.[10]

An additional advantage of the epidural part of the combined technique is the low blood loss that has been demonstrated under regional techniques for surgical procedures possibly as a result of the low central venous pressure associated with epidural anesthesia.[8,9] For the

operations reviewed, an average of 300 mL of blood loss occurred.

The potential for decreased blood pressure with epidural anesthesia must be considered and adequate volume support given. All patients in this series had preoperative assessment of their volume status by clinical and laboratory criteria and correction of deficits. This was done without using a Swan-Ganz central venous catheterization prior to operation, although a central venous line was placed intraoperatively in all patients. This retrospective analysis indicated that this approach was adequate. Stable intraoperative hemodynamics were achieved except for one episode of hypotension responding to ephedrine. There were no other complications associated with the epidural analgesic technique. Mention should be made of the potential complication of epidural hematoma; this complication is rare. In the series of Bonica and Anderson,[24] the risk was less than 0.01%. It did not occur in this series.

In conclusion, the combined technique of epidural analgesia with light general anesthesia provided satisfactory anesthesia for thoracic operations in a high-risk group of patients undergoing thoracic surgical procedures. This approach may be preferable to general anesthesia alone, but only a prospective randomized study could definitively demonstrate such superiority.

Nosocomial Infection and Fatality in Medical and Surgical Intensive Care Unit Patients

Donald E. Craven, MD; Laureen M. Kunches, RN, MPH; Deborah A. Lichtenberg, RN; Nancy R. Kollisch, MD; M. Anita Barry, MD; Timothy C. Heeren, PhD; William R. McCabe, MD

We prospectively studied 526 patients admitted to the medical intensive care unit (MICU) and 799 patients admitted to the surgical intensive care unit (SICU) at a municipal hospital over a 20-month period. Rates of nosocomial infection were higher in the SICU patients (31% vs 24%). The SICU patients had more urinary tract infections, bacteremias, and wound infections, and the MICU patients were older, had higher acute physiology scores on admission and were more often admitted with shock or coma. The SICU patients were more likely to have received prior antibiotic therapy and had significantly higher numbers of endotracheal tubes, arterial lines, central venous lines, and indwelling bladder catheters. On the 23 variables univariately associated with nosocomial infection, only five remained significant after entry into stepwise regression models. The MICU patients had a higher fatality rate in the MICU than did the SICU patients (18% vs 10%), but the relative risk of a death following nosocomial infection was 3.5 for both groups. Thirty variables were significantly associated with hospital fatality; nine remained significant after analysis by stepwise logistic regression (*Arch Intern Med* 1988;148:1161-1168).

Use of Sequential B-Mode Ultrasonography to Manage Abdominal Aortic Aneurysms

Fred N. Littooy, MD; George Steffan, PA; Howard P. Greisler, MD; Theresa L. White, RN; William H. Baker, MD

• The utility and safety of sequential B-mode ultrasonography to treat male patients with small (<6.0 cm in diameter) abdominal aortic aneurysms (AAAs) were studied retrospectively in 149 consecutive patients. Sixty-three of these patients have had operative repair of the AAA. Eighty-six remain unoperated on. Mean growth rate was 0.79 cm/y (1.06 cm/y in the operated-on group and 0.36 cm/y in the unoperated-on group). Seven patients sustained rupture of the AAA during follow-up and 4 patients died as a consequence of elective repair, for a combined mortality rate of 7.4% (11/149). Only one AAA that was less than 5.0 cm ruptured. This has proved to be an effective way to manage AAAs in this population.

(*Arch Surg* 1989;124:419-421)

The decision to repair an abdominal aortic aneurysm (AAA) electively depends on the risk of that operative repair vs the risk that an untreated aneurysm will rupture. Most patients with AAAs are in the sixth and seventh decades of life, and many have debilitating diseases that limit life expectancy and increase the operative risk. Separate studies by Szilagyi et al[1] and Darling[2] pointed out that the risk of rupture increases as the diameter of the aneurysm increases. B-mode ultrasonography gives us an accurate diagnostic tool to determine the size of the aneurysm and to follow its growth over time. Elective operative repair of aneurysms, introduced in 1952 by Dubost et al,[3] is now carried out with a 1% to 5% mortality rate in many centers.[4-6] Using the information on the natural history of aortic aneurysms based on size of the aneurysm and the ability to diagnose and size the aneurysm accurately, the surgeon is better able to decide on operative vs nonoperative therapy. This study was undertaken to assess the usefulness and safety of this approach in a male population.

PATIENTS AND METHODS

For the years 1977 through 1987, we studied 149 consecutive male patients retrospectively from the Hines (Ill) Veterans Administration Medical Center. Each patient had a diagnosis of AAA and had at least two sequential B-mode abdominal ultrasonograms to evaluate that AAA. The abdominal aorta had to measure at least 3.0 cm in greatest diameter for that patient to be included in the study. Ultrasonography was performed with a commercial real-time sector scanner from 1982 to 1987. Prior to that, a static scanner was used. Anteroposterior and transverse diameters were measured, and we used the larger of the two measurements to size the aneurysm. Mean growth rates were determined by the change in size over time of the AAA between the first and last ultrasonographic measurements (centimeters per year). Patients with AAAs of less than 5.0 cm in greatest diameter were followed up every 3 to 6 months with serial ultrasonography and advised to have an elective repair of the aneurysm if it reached 5.0 cm in greatest diameter or if symptoms developed in the patient. In some patients who were considered to be high risk, we would often delay operative repair until the aneurysm reached 6.0 cm in diameter.

Accepted for publication December 29, 1988.

From the Loyola University Medical Center, Maywood, Ill (Drs Littooy, Greisler, and Baker); and the Hines (Ill) Veterans Administration Hospital (Drs Littooy and Greisler, Mr Steffan, and Ms White).

Read before the 12th Annual Surgical Symposium of the Association of Veterans Administration Surgeons, Minneapolis, Minn, May 12, 1988.

Reprint requests to Department of Surgery, Loyola University Medical Center, 2160 S First Ave, Maywood, IL 60153 (Dr Littooy).

We then examined expansion rates based on grouping by the initial size of the aneurysm (ie, 3.0 to 3.9 cm; 4.0 to 4.9 cm). We further broke this down into patients who have had operative repair vs those not yet operated on. Further study included the rate of rupture with this approach and the results of operative therapy. All operations were performed by general surgical residents at the fourth- or fifth-year level or by peripheral vascular fellows assisted by a trained vascular surgeon.

During the 10-year period (1977 through 1987), 149 male patients met the criteria for inclusion in the study. The mean age was 68.1 years (range, 48 to 92 years). Of the 149 patients, 86 have had only serial ultrasonography. The remaining 63 patients have undergone operative repair of the AAA.

RISK FACTORS

Atherosclerotic risk factors for the group as a whole included cerebrovascular accident in 30 (20.1%), congestive heart failure in 43 (28.9%), heart disease as defined by myocardial infarction (MI), angina pectoris, congestive heart failure, abnormal electrocardiogram, or arrhythmias in 103 (69.1%), hypertension as defined by diagnosed and medically treated hypertension in 92 (61.7%), smoking in 137 (91.9%), and diabetes mellitus in 18 (12.1%).

Other risk factors included chronic obstructive pulmonary disease in 47 (31.5%) and chronic renal failure (creatine value >141 μmol/L) in 36 (24.2%). Risk factors, particularly the presence of heart disease (79% vs 55%), creatine values greater than 141 μmol/L (31% vs 19%), and cerebrovascular accident (26% vs 11%), were more pronounced in the nonoperated-on patients.

DIAGNOSIS

Abdominal aortic aneurysms were detected by several means in our population of 149 patients. Ninety-four (63%) were picked up on physical examination. The remainder were found during workup for other diagnoses. Diagnostic roentgenograms of the abdomen, back, or pelvic regions detected calcium in the walls of the AAA in 22 patients (14.8%). Ultrasonographic studies in 24 patients (16.1%) and computed tomographic scans in 4 patients (2.7%) delineated the AAA. Angiography for occlusive disease or other problems revealed AAAs in 3 patients (2.0%). One additional AAA (0.7%) was found on exploration of the abdomen during surgery for other problems.

EXPANSION RATES BY SERIAL ULTRASONOGRAPHY

To date, 149 patients have had at least two serial ultrasound examinations. Eighty-six are in the unoperated-on group, and 63 have gone on to have operative repair. The expansion rate for the group as a whole and for the nonoperated-on and operated-on patients as separate groups is depicted in Table 1. The mean growth rate overall is 0.79 cm/y (range, 0 to 6.0 cm). In patients not yet operated on, the growth rate has been 0.36 cm/y vs 1.06 cm/y in the operated-on group. This difference in growth rates between operated-on and unoperated-on patients is noted throughout the different groups based on initial size of the aneurysm. In addition, initial size of the aneurysm had no effect on expansion rate in the patient population as a whole or when broken down into operated-on and unoperated-on patients. The increased expansion

rate seen in patients coming to operation is likely not related to initial size, as 41 (65.1%) of the 63 operated-on patients had aneurysms of less than 5.0 cm in greatest diameter at the time of initial diagnosis. In fact, 24 of those patients had AAAs of less than 4.0 cm in diameter initially.

OUTCOME

In the 86 unoperated-on patients, the mean length of follow-up was 41.5 months (range, 1 to 156 months). Fifty-three (61.6%) are still alive after a mean follow-up of 44.8 months (range, 10 to 156 months). Thirty-three nonoperated-on patients with a mean follow-up of 36.2 months (range, 1 to 82 months) have died. Causes of death in this group are rupture of AAA in 4 (12.1%), coronary artery disease in 14 (42.7%), cancer in 5 (15%), other causes in 8 (24.2%), and unknown in 2 (6%). No patient died of a cerebrovascular accident. Of the patients who died because of a ruptured AAA, 2 had severe medical problems but were offered operative repair. They refused and died at 26 and 33 months, respectively, after their initial diagnosis and both had AAAs with a diameter of greater than 6.5 cm. Of the other 2 patients, 1 had severe medical risks (congestive heart failure and renal failure), and his AAA was only 4.6 cm in diameter. He represents the only AAA with a diameter of less than 5.0 cm known to have ruptured. The last patient had multiple medical problems with an AAA that eventually reached 5.5 cm in diameter and was not offered operative repair. He died 78 months after diagnosis.

Of the 63 patients who had operative repair, the mean time from diagnosis to operation was 25.4 months (range, 1 to 78 months). Indication for operative repair included the following: size alone in 43 patients (68.2%), symptomatic abdominal or back pain without rupture in 11 (17.4%), claudication in 4 (6.4%), renal-vascular hypertension in 2 (3.2%), and a ruptured aneurysm in 3 (4.7%). Of these indications, 58 patients underwent surgery that was considered purely elective. The repair in 2 patients was done in less than 24 hours after hospital admission for acutely symptomatic but nonruptured AAAs, and three repairs were done for ruptured AAAs. We were able to use tube graft replacement in only 9 patients (14.3%), and we had to extend the bifurcation replacement grafts to the level of the groin on at least one side in 16 patients (25.4%). There were only two long-term graft complications: one pseudoaneurysm and one aortoenteric fistula.

Operative mortality rates are summarized in Table 2. In the 58 patients who underwent elective surgery, there were two postoperative deaths (3.4%). One was due to an MI 2 weeks postoperatively in a patient with no previous coronary artery disease, and the other was secondary to bleeding complications intraoperatively. Both patients who underwent surgery urgently for acutely symptomatic but nonruptured AAAs died of MIs. Combining these two groups as some do yielded an operative mortality rate of 6.67% for nonruptured AAAs.

All three patients operated on for a ruptured AAA died: one because of an intraoperative MI, one because of refractory hypotension, and the other 33 days postoperatively from other medical conditions. The patient with the intraoperative MI was a high-risk patient who had a large thoracoabdominal aneurysm with severe visceral, renal, and peripheral occlusive disease. Previously he had been considered to have an inoperable aneurysm. In the second patient who died, the aneurysm ruptured during angiography in preparation for an elective repair. The third patient was severely debilitated in the hospital for 8 months and the aneurysm ruptured while he was in the hospital. Mean long-term follow-up in the 57 survivors was 42.8 months (range, 1 to 126 months). Forty-three (75.4%) remain alive. The cause of 14 late deaths include coronary artery disease in 5 (35.7%), carcinoma in 3 (21.4%), other in 5 (35.7%), and unknown in 1 (7.14%).

In summary, seven ruptured AAAs (4.7%) have occurred in the total population of 149 patients (Table 3). Three of the seven patients reached the operating room. It is likely that one of these ruptures was caused by the catheter during an aortogram being done to evaluate the aneurysm in a patient who was to undergo elective surgery. Two ruptures occurred in patients who were high risk and refused the offered surgical therapy. The other four ruptures occurred in patients who were not considered to be surgical candidates based on severe coexisting disease or functional status of the patient.

Table 1.—Expansion Rate of AAA by Serial Ultrasonography*

Initial Size of AAA, cm	All Patients (N=149)	Average Expansion Rate, Mean cm/y: Nonoperative Repair (n=86)	Average Expansion Rate, Mean cm/y: Operative Repair (n=63)
2.0-2.9	0.64 (3)	0.36 (1)	0.79 (2)
3.0-3.9	0.50 (63)	0.26 (41)	0.86 (22)
4.0-4.9	1.01 (50)	0.40 (33)	1.1 (17)
5.0-5.9	0.96 (22)	0.32 (7)	1.2 (15)
6.0-6.9	0.86 (6)	1.1 (2)	0.80 (4)
7.0-7.9	0.0 (2)	0.0 (1)	0.0 (1)
8.0-8.9	0.0 (2)	0.0 (1)	0.0 (1)
>9.0	2.2 (1)	. . .	2.2 (1)
Overall	0.79 (149)	0.36 (86)	1.06 (63)

*AAA indicates abdominal aortic aneurysm. Number in parentheses indicates number of patients.

Table 2.—Operative Mortality

	No. of Patients	Deaths, No. (%)
Nonruptured	60	4 (6.6)
Elective	58	2 (3.4)
Urgent	2	2 (100)
Ruptured	3	3 (100)

Table 3.—Summary of Patients Whose AAAs Rupture*

Patient	Size at Last Examination, cm	Total FU From Dx to Rupture, mo	Comments†
A	4.6	6	1, 5, 6
B	5.5	78	1, 3, 5
C	6.6	26	1, 2, 5
D	7.4	33	1, 2, 5
E	6.5	18	1, 3, 4, 5
F	6.3	24	1, 4, 5, 8
G	10.0	22	1, 3, 4, 5, 7

*AAA indicates abdominal aortic aneurysm; FU, follow-up; and Dx, diagnosis.

†1 indicates high medical risk; 2, refused surgery; 3, surgery not offered electively; 4, emergency repair; 5, died as consequence of rupture; 6, only AAA of less than 5.0 cm in size to rupture; 7, thoracoabdominal aneurysm; and 8, ruptured during aortogram.

COMMENT

Size of an AAA correlates closely with the lethal potential of that aneurysm. Assuming a 5% operative mortality

rate, the risk of rupture of an AAA becomes greater than the risk of elective repair when the aneurysm reaches 5 cm in greatest diameter.[2] This is certainly true in basically healthy patients in whom the risk may be closer to 1% to 2% with careful perioperative management, as so well described by Whittemore et al.[4] Using these same principles, Hollier et al[7] treated very high-risk operative candidates with an exceptional operative mortality rate of 6%. Of course patients who are expected to die of their coexisting medical problems within the same time frame are not surgical candidates. Two recent studies, one by Cronenwett et al[8] and one by Sterpetti et al,[9] analyzed several variables that are associated with rupture or the enlargement rate of small AAAs. In the study of Cronenwett et al of actuarial rupture rates, only three covariables, diastolic blood pressure, initial aneurysm anteroposterior diameter, and degree of chronic obstructive pulmonary disease, were independently predictive of rupture. They noted an increase in rupture rate from 2% to 100% when these three risk factors were either all absent or all present, respectively. Sterpetti et al demonstrated only two variables to be independent predictors of mean enlargement rate: (1) absence of distal arterial occlusive disease and (2) the ratio of the diameter of the aneurysm to the diameter of normal aorta above the aneurysm. Although both of these studies are retrospective, they do indicate that predicting the possibility of rupture perhaps hinges on more than size of the aneurysm alone. Therefore, even a high-risk operative candidate with a small (<6.0-cm-in-diameter) AAA may still be better served with an operation if we had a better understanding of the other factors that may increase the potential for rupture of a particular AAA.

At the present time, size of the AAA is our guide to decisions in operative repair; therefore, it is important to have a reproducible, accurate, noninvasive, relatively inexpensive means of sizing the AAA. Proper preparation of the patient and use of B-mode ultrasonography by experienced examiners gives us that tool to make measurements within 3 mm of actual size.[10] Some advocate using computed tomographic scanning in this evaluation, because it is more accurate, gives more information about the thickness of the wall, relationship of the aneurysm to the renal or visceral vessels, existence of iliac aneurysms, etc.[11] Nevertheless, it is more expensive and uses radiation. Angiography, whether standard or digital subtraction,[12] is invasive, expensive, and occasionally nondiagnostic. For long-term follow-up of small AAAs, serial B-mode ultrasonography is the tool of choice in our hands.

Much has been learned about growth rates of AAAs from the longitudinal ultrasonographic studies of patients with small AAAs (3 to 6 cm in diameter) by Bernstein and Chan.[6] Their data on 99 high-risk patients followed up by ultrasonography documented a mean expansion rate of 0.4 cm/y. This rate has been documented by others as well.[8,9] Measurement of the growth rate of small aneurysms in our institution showed some surprising findings. Although the growth rate in 86 yet unoperated-on patients was 0.36 cm/y and very similar to the results of Bernstein and Chan, the growth rate in 63 patients eventually operated on was 1.06 cm/y. This made the growth rate for the study group of 149 patients as a whole 0.79 cm/y. Since nearly two thirds of the patients who underwent surgery had small aneurysms (3 to 5 cm) when initially seen, and because the growth rate was basically the same despite the grouping by initial size, it would appear that some other factors were at work. Although we did not analyze the potential risk factors, it should be noted that the incidence of hypertension, chronic obstructive pulmonary disease, and renal failure was actually higher in the unoperated-on group. Perhaps as suggested in work by Busittil et al,[13] increased collagenase activity may play a role in the increased expansion rate. Perhaps this increased activity is related to other risk factors that may increase proteolytic activity such as collagenase.

Finally, is it safe to base our treatment of patients with small AAAs (<5.0 cm in greatest diameter) on serial ultrasonography? Bernstein and Chan[6] used serial ultrasonography in the previously mentioned 99 high-risk patients with small aneurysms up to 6 cm in size and operated when the aneurysms reached 6.0 cm in size or when symptoms developed. Using that approach 4 (4%) have died of elective aneurysm repair or rupture. Only 3 of their patients had ruptures during follow-up: 2 had AAAs of less than 6.0 cm in size, one of which was less than 5.0 cm in size. His 5-year cumulative survival rate was 63.7%. Although we did not calculate cumulative survival rates, 61.6% of our nonoperated-on patients are alive after a mean follow-up of 44.8 months, and 68.3% of the operated-on patients are alive at a mean follow-up of 42.8 months.

In comparison, seven patients in our series (4.7%) had ruptures during follow-up. These were summarized earlier in Table 3. Our mortality rate in elective aneurysm repair was 3.4% (2/58) or 6.6% (4/60) if the urgent, unruptured aneurysms are included. The overall mortality rate from rupture or elective aneurysm repair of 7.4% (11/149) compares favorably with that of the series of Bernstein and Chan[6] of 4%. Using a threshold of 5.0 cm greatest diameter in the low- or medium-risk patient and 6.0 cm greatest diameter in the high-risk patient appears to be a safe approach in the treatment of these patients. As we gain a better understanding of the effect of risk factors other than size of the aneurysm and improve perioperative management, we believe we can treat these patients even more safely.

Pelvic Fracture Hemorrhage

Priorities in Management

B. Mark Evers, MD; Henry M. Cryer, MD; Frank B. Miller, MD

• Hemorrhage remains the leading cause of mortality in patients with severe pelvic fractures. To evaluate diagnostic and treatment priorities for this problem, we retrospectively reviewed 245 consecutive patients admitted to our institution with pelvic fractures. Supraumbilical diagnostic peritoneal lavage (DPL) was grossly positive in 27 patients, and eight (30%) of these had life-threatening intra-abdominal hemorrhage identified at laparotomy. No patient with a positive DPL by count alone had life-threatening intra-abdominal hemorrhage. Pelvic fracture stabilization with early external pelvic fixation was associated with less requirement for blood transfusion (10 ± 1 U) than with the pneumatic antishock garment (17 ± 3 U). Nine patients with pelvic arterial injuries underwent angiographic embolization, and eight patients died (89%). We conclude that pelvic angiography should be performed before laparotomy in hemodynamically unstable patients with pelvic fracture, unless the DPL is grossly positive.

(*Arch Surg* 1989;124:422-424)

Massive extraperitoneal hemorrhage from pelvic fracture remains a significant problem. Despite the institution of various protocols, including the use of the pneumatic antishock garment (PASG), pelvic external fixation, and angiography with selective embolization, there remains a subgroup of patients with severe pelvic fractures in whom the mortality ranges from 25% to 39%, with the majority succumbing to exsanguination.[1-5]

This challenging subgroup of multiply injured patients requires rapid evaluation, identification, and control of the source of major blood loss. Several authors have recently suggested that to decrease the mortality in this subset of patients, a more aggressive approach is necessary. Panetta and associates[6] have advocated the use of early angiography in all patients with pelvic fracture requiring more than 4 U of blood within 24 hours or more than 6 U within 48 hours. The Gilliland group[5] has proposed that angiography and selective embolization should precede laparotomy even when diagnostic peritoneal lavage (DPL) is positive. And Moreno et al[2] have submitted that angiography should precede laparotomy when a DPL is positive by count but that laparotomy should be performed first when the lavage is grossly positive. Though a more aggressive protocol is clearly indicated, the proper sequence of diagnostic and therapeutic maneuvers to determine the major source of bleeding remains controversial. The current study was undertaken to help clarify this important problem.

PATIENTS AND METHODS

Between January 1983 and December 1986, our institution admitted 245 consecutive patients with pelvic fractures, excluding isolated acetabular fractures. Patient charts were retrospectively reviewed for mechanism of injury, age, length of hospital stay, admission blood pressure and heart rate, results of DPL, transfusion requirements, treatment modality, and Injury Severity Score.

When intra-abdominal injury was suspected, DPL was performed supraumbilically using the open technique. The lavage was considered grossly positive when greater than 10 mL of blood was aspirated from the abdominal cavity and count positive when the red blood cell count exceeded 0.0001×10^{12}/L, or when the white blood cell count was greater than 0.0005×10^{9}/L in the lavage fluid. Laparotomy was considered positive when an intraperitoneal cause of bleeding was found.

Patients treated with PASG had the extremity compartments inflated to 50 mm Hg and the abdominal compartment to 40 mm Hg. The PASGs were deflated after eight hours if the patient remained hemodynamically stable and without the need for continued blood replacement. Patients treated with immediate external pelvic fixation instead of PASG had the external fixator applied within 12 hours of admission. Pelvic angiography was performed percutaneously using the Seldinger technique. Selective arterial embolization was performed using absorbable gelatin sponge (Gelfoam) and/or stainless steel coils.

Statistical analysis comparing transfusion requirements in the PASG and fixator groups was by the Behrens-Fisher t test, with Welch degrees of freedom, for groups of unequal size. Data were reported as the mean ± SEM. To determine the association between DPL results and intra-abdominal injury, the Yates χ^2 was used and the degree of correlation quantitated with the φ_2 correlation coefficient.[7]

RESULTS

There were 153 men and 92 women with a mean age of 36 years (range, 14 to 87 years) in our patient group. Mechanism of injury was motor vehicular in 143 (58%), auto-pedestrian in 39 (16%), fall in 27 (11%), crush in 19 (8%), motorcycle in 14 (6%), bicycle in two, and sledding in one. Overall mortality was 14% (35/245), with hemorrhage the leading cause (Table 1). When hemorrhage was the cause of death, the primary site of bleeding was the pelvis in 61% (11/18) and the pelvis and the abdomen combined in 22% (4/18). The Injury Severity Score is correlated with mortality in Table 2.

No blood transfusion was required in 113 patients (46%). Fifty-one patients (21%) required 1 to 3 U of blood, 37 patients (15%) required 4 to 9 U of blood, and 10 U or more of blood were required for hemodynamic stability in 44

*DPL indicates diagnostic peritoneal lavage.
†Severe hemorrhage from injury in parentheses.

Management protocol for hemodynamically unstable patient with pelvic fracture.

patients (18%). Patients requiring 4 U or more of blood were considered to have a major hemorrhage.

Supraumbilical DPL was performed in 83 patients. The lavage was negative in 37 of these patients, with no false-negative examinations. The DPL was positive in 46 patients; no intra-abdominal injury was found at laparotomy in four of these patients (false-positive rate, 9%). In this group of patients with pelvic fracture, DPL had a sensitivity of 100% and a specificity of 91%. The χ^2 for DPL accuracy was 59.25 ($P<.001$), and the φ_2 correlation coefficient was .92, demonstrating an excellent association.

Intra-abdominal injuries in relation to DPL findings are given in Table 3. Twenty-seven of the 46 positive lavages were grossly positive, and life-threatening intra-abdominal hemorrhage was found at laparotomy in eight (30%). None of the 19 patients with a positive DPL by count alone had significant ongoing intra-abdominal hemorrhage at laparotomy. An additional 14 patients underwent exploratory laparotomy for indications other than a positive DPL. Nine of them had a positive cystogram and had laparotomy for bladder repair. Four patients underwent laparotomy based on clinical criteria, and an additional patient had laparotomy based on radiographic findings of a ruptured hemidiaphragm. None of these 14 patients had life-threatening intraperitoneal bleeding at laparotomy. There were eight negative laparotomies, including four false-positive lavages and four patients operated on for physical findings. Five (63%) of these eight patients with negative laparotomies died.

After control of abdominal hemorrhage, we performed pelvic fracture stabilization to control bleeding from bony fragments by either PASG (24 patients) or immediate external pelvic fixation (23 patients). Mean blood transfusion requirements after fracture stabilization with PASG were 23 ± 3 U compared with 8 ± 1 U with the external fixator. However, these groups were not strictly comparable because the fixator was initially used on more patients in hemodynamically stable condition. In addition, all but one of the patients with pelvic arterial injuries were in the PASG group. When all patients who required less than 4 U of blood and all patients with major pelvic arterial injuries were excluded, 17 patients treated with PASG required 17 ± 3 U after fracture stabilization and six died of pelvic hemorrhage. On the other hand, the 14 patients treated with the external fixator required 10 ± 1 U ($P<.05$) and none died.

Sixteen patients had arteriography for continued hemodynamic instability after laparotomy and/or pelvic stabilization. Arterial injuries were identified in nine patients. Eight of these underwent successful embolization. Eight (89%) of the nine patients with pelvic arterial injury died. Four patients died early of exsanguination or persistent hemorrhagic shock and four died later of multiple system organ failure (MSOF) and sepsis.

Seven patients had open wounds communicating with the pelvic fracture. Three patients were bleeding massively from these wounds. Bleeding stopped with local wound packing alone in one patient; local wound packing plus pelvic fixation in a second patient; and local wound packing, PASG, and arteriographic embolization in the third patient.

The third patient died of MSOF and sepsis from an infected pelvic hematoma. This was the only death in the open fracture group.

COMMENT

Massive retroperitoneal hemorrhage from pelvic fractures remains a formidable problem confronting the trauma surgeon. Despite the use of the PASG,[1,8] external pelvic fixation,[9] and invasive angiography with selective embolization of pelvic arterial injuries,[6,10,11] there remains a subset of patients with pelvic fracture who die early as a result of hemorrhage or die later from sepsis-induced MSOF probably related to prolonged hemorrhagic shock. To improve outcome in this subset of patients, the source of major hemorrhage must be rapidly identified and controlled before massive blood loss and coagulopathy occur.

Our data were consistent with the literature[2,12-14] and demonstrated that peritoneal lavage is an extremely accurate test in ruling out intra-abdominal injury when it is negative. These data also indicated that a grossly positive DPL is an indicator of possible life-threatening intra-abdominal hemorrhage mandating immediate laparotomy. In our series, eight (30%) of the 27 patients with grossly positive lavages had life-threatening intra-abdominal hemorrhage at laparotomy. The Moreno group[2] found life-threatening intra-abdominal hemorrhage in 84% of their patients with severe pelvic fractures and grossly positive DPL. Conversely, no patient in our series with a positive lavage by count alone had significant ongoing intra-abdominal hemorrhage. Therefore, in the patient in hemodynamically unstable condition who has a positive DPL by count alone, it is unlikely that the major source of bleeding is from intra-abdominal hemorrhage, and, in this instance, we would advocate immediate fracture fixation followed by arteriography and then laparotomy.

The high mortality associated with negative laparotomy in patients in hemodynamically unstable condition with pelvic fracture has previously been emphasized.[5,13] Our 63% mortality with negative laparotomy confirms these reports. Four of these patients in hemodynamically unstable condition underwent exploratory laparotomy without a DPL for physical findings suggestive of intra-abdominal injury. Data suggested that physical examination of the abdomen in patients with pelvic fracture is unreliable. On the other hand, DPL has been extremely accurate in ruling out intra-abdominal injury in our patients and in all other series reported.[2,12-14] Therefore, we believe that a DPL should be performed before laparotomy in all patients in hemodynamically unstable condition with pelvic fractures.

Pelvic fracture stabilization has been shown to tamponade bleeding from multiple small- and medium-sized vessels within disrupted cancellous bone,[15] and we have previously reported a significant reduction in mortality with the use of PASG. There has been recent evidence that immediate external pelvic fixation is as good as or better than PASG for the control of pelvic hemorrhage.[2,9,16,17] In the present study the numbers were relatively small and the analysis was retrospective, but when attempts were made to make these two groups as comparable as possible, our data agreed with the growing concept that the external pelvic fixator may be more efficacious than PASG in stopping nonarterial pelvic fracture hemorrhage. The fixator has the added advantages of earlier patient mobilization and rehabilitation without interfering with any surgical procedures.[9,16,17]

Our results with arteriographic embolization of pelvic arterial injuries (89% mortality) are much worse than those reported by others. Matalon and associates[11] reported a 50% mortality in 20 patients who had angiographic embolization of pelvic arterial bleeding and noted that only one patient died of presumed continued pelvic hemorrhage. Panetta et al[6] reported 11 deaths (35%) in 31 patients who had pelvic arterial injuries treated by angiographic embolization. Four patients died of refractory hemorrhagic shock in spite of successful angiographic embolization in our series, which suggests that we were performing angiography too late. Additionally, we believe that a prolonged low-flow state secondary to persistent, uncontrolled hemorrhage contributed to the late development of MSOF and sepsis in four other patients. The mean elapsed time from admission to arrival in angiography in our series was 4 ± 0.5 hours. Therefore, our data suggest that earlier angiographic control of pelvic arterial hemorrhage is necessary to reduce mortality in this group of patients.

Based on our data, we have developed the following protocol to prioritize the management of patients in hemodynamically unstable condition with pelvic fractures (Figure). Supraumbilical DPL should be performed in the operating room and, if the lavage aspirate is grossly positive, then a rapid abdominal exploration with control of intra-abdominal bleeding should be performed. In our opinion, computer tomographic scanning is too time-consuming to be efficient in the evaluation of these complex patients. Pelvic fixation should be applied during or after laparotomy if a pelvic hematoma is present. Angiography with selective arterial embolization is then performed if hemodynamic instability persists or if a large and/or expanding retroperitoneal hematoma is found. If the lavage is positive by count alone, then pelvic fixation and immediate angiography should be performed first, followed by laparotomy. If the lavage is negative, patients should undergo immediate pelvic stabilization followed by angiography.

Anastomotic Tensile Strength Following In Situ Replacement of an Infected Abdominal Aortic Graft

Raymond Vetsch, MD; Dennis F. Bandyk, MD; David D. Schmitt, MD; Thomas M. Bergamini, MD; James D. Storey, MD; Jonathan B. Towne, MD

• The tensile strength and histologic features of anastomotic bonding were studied prior to and following in situ replacement of aortic vascular prostheses infected by *Staphylococcus epidermidis*. Sterile (n = 6) and infected (n = 19) Dacron grafts were used to replace the abdominal aorta of 25 dogs. After five weeks, grafts were explanted, and peak tensile force (measured in kilograms) required for anastomotic disruption was measured using a linear gain tensiometer. Anastomotic tensile strength (mean ± SEM) of infected grafts (5.4 ± 0.5 kg) was decreased when compared with that of sterile, control grafts (9.0 ± 0.9 kg). The decreased anastomotic tensile strength of infected grafts was the result of an inflammatory aortitis adjacent to the suture line. Only grafts infected with the study strain of bacteria demonstrated signs of infection. In 19 dogs, the graft infection was treated by graft excision, antibiotic administration, and in situ graft replacement (Dacron or polytetrafluoroethylene prostheses). After five weeks and 12 weeks, anastomotic tensile strength of polytetrafluoroethylene (10.6 ± 0.6 kg) and Dacron (10.8 ± 0.5 kg) replacement grafts was similar to that of uninfected control grafts. In situ replacement of vascular prostheses infected by *S epidermidis* can result in graft healing with normal anastomotic bonding.

(*Arch Surg* 1989;124:425-428)

Late-appearing graft infection and anastomotic pseudoaneurysm formation have not decreased as clinical problems of using vascular prostheses despite improvements in suture and graft fabrication and despite the routine use of perioperative antibiotic prophylaxis. Graft infection or anastomosis dehiscence develops in approximately 5% of patients after implantation of a vascular prosthesis.[1-3] The pathogenesis of late graft healing complications, especially those involving the common femoral artery, appear to be the result of infection caused by slime-producing strains of *Staphylococcus epidermidis*.[4,5] When vascular prostheses are colonized by low-virulence bacteria, such as *S epidermidis*, the microorganisms are harbored and survive within a biofilm adherent to the prosthetic surface. This bacterial biofilm incites a chronic inflammatory process adjacent to the prosthesis with autolysis of perigraft tissue and the adjacent artery wall, which, with time, results in the anastomotic and perigraft healing complications associated with late graft infection. The predilection of prosthetic implants for staphylococcal colonization, especially *S epidermidis*, is well documented. *Staphylococcus epidermidis* can be cultured from diseased artery walls and groin lymph nodes in one third of patients undergoing vascular prosthesis implantation,[6,7] from 75% of prostheses revised for anastomotic pseudoaneurysm,[8] and from 80% of aortofemoral prostheses removed because of infection.[4]

In a canine model of aortic graft infection due to *S epidermidis* that mimicked the anatomic and microbiologic characteristics of late graft infection in humans, we found that in situ replacement of infected grafts resulted in early (three weeks) graft healing, but positive cultures of replacement grafts were obtained in 30% of the animals.[9] The study did not address the late outcome of graft colonization or compare anastomotic bonding of infected grafts with that of in situ replacement grafts. Since life- and limb-threatening complications of *S epidermidis* graft infections are associated with suture-line dehiscence, measurements of anastomotic tensile strength are of critical importance in assessing the efficacy of in situ graft replacement as a treatment option for this prosthetic infection.

In this study, we utilized our canine model of *S epidermidis* prosthetic graft infection to evaluate the tensile strength of graft-to-artery anastomoses. Anastomotic tensile strength of sterile control, infected, and in situ replacement grafts was correlated with clinical signs of infection (eg, perigraft exudate, graft incorporation, anastomotic aneurysm), aortic wall histologic features, interval following graft replacement, and microbiologic evidence of infection. Confirmation of normal anastomotic binding following in situ graft replacement of an established *S epidermidis* graft infection would favor the use of this surgical approach, as compared with the increased morbidity associated with total graft excision, artery ligation, and extra-anatomic arterial bypass.

MATERIALS AND METHODS

Canine Model

Using sterile surgical technique, 25 female conditioned mongrel dogs (weighing 20 to 25 kg) underwent interposition grafting of the infrarenal aorta with a sterile (n = 6) or infected (n = 19) Dacron vascular prosthesis (6-mm diameter, 5-cm length). A commercially available double-velour, knitted Dacron graft (Meadox Medicals Inc, Oakland, NJ) was implanted. In situ replacement of the infected grafts was performed using an identical sterile Dacron graft or a 6-mm-diameter, expanded polytetrafluoroethylene (PTFE) (Gore-Tex, W. L. Gore & Associates Inc, Elkton, Md) vascular prosthesis. These graft types have been used in prior in vitro and in vivo studies of bacterial adherence to vascular prosthetic surfaces.[9] Of note, both graft types have been shown in a canine model to result in comparable graft-to-artery bonding strengths at three to nine months after implantation.[10] All animals received humane care and our methods complied with the *Principles of Laboratory Animal Care* and the *Guide for the Care and Use of Laboratory Animals* (National Institutes of Health [Bethesda, Md] publication No. 80-23, revised 1978).

The technique of graft colonization with a slime-producing strain

of *S epidermidis* (American Type Culture Collection 35983) has been previously described.[9] In brief, the Dacron grafts were immersed in the inoculating solution (7.0 $\log_{10}$ colony-forming units [CFUs] of *S epidermidis*) for 24 hours at room temperature prior to implantation. During the incubation period, a bacteria-laden biofilm formed on the prosthetic surface with a mean bacterial concentration of approximately 5×10^4 CFU/cm^2 of graft material.[9] The *S epidermidis* study strain was susceptible to cefazolin sodium (minimum inhibitory concentration, <0.25 mg/mL).

Graft Implantation

The dogs were anesthetized with intravenous pentobarbital sodium (20 mg/kg), intubated, and mechanically ventilated with a volume-cycled respirator. The abdominal wall was shaved, scrubbed with povidone-iodine detergent, painted with 1% povidone-iodine solution, and covered with povidine-iodine impregnated plastic drapes. No antibiotics were administered during the perioperative period. A midline incision was used for exposure of the infrarenal aorta. A 3-cm length of aorta was dissected from surrounding retroperitoneal structures, and lumbar arteries in the mobilized segment were ligated. Systemically administered heparin was not used during the period of aortic cross-clamping. Grafts were preclotted and anastomosed end-to-end to the transected aorta with continuous 6-0 polypropylene sutures, using ×2.5 optical magnification. The retroperitoneum was covered over the graft with a continuous suture (3-0 chromic catgut), and the midline wound was sutured closed.

Graft Explantation and Replacement

Five weeks after implantation, the control and infected aortic grafts were exposed through the previous midline incision using sterile surgical technique. Cefazolin sodium (25 mg/kg) was administered intravenously one hour before the operation to minimize colonization of replacement grafts. In addition, animals undergoing in situ replacement for five weeks were administered cefazolin sodium (25 mg/kg) intramuscularly at 12-hour intervals for ten days, while animals undergoing in situ PTFE replacement for 12 weeks were administered cefazolin sodium (25 mg/kg) intramuscularly at eight-hour intervals for one day (based on a prior study protocol[9]). No antibiotic was administered to dogs undergoing excision of sterile, control Dacron grafts.

After proximal and distal control of the grafted aorta was obtained, the Dacron graft was exposed and examined for signs of infection (eg, perigraft inflammation/fluid, perigraft cavity formation, and/or anastomotic dehiscence). Swabs of the perigraft fluid or the external graft surface were obtained and cultured aerobically on tryptic soy agar with 5% sheep's blood. The graft was then totally excised, including anastomotic sites and 1 cm of adjacent aorta, with care taken not to disrupt the fibrous capsule surrounding the anastomoses. A 1-cm length of graft without adherent thrombus, perigraft capsule, or adjacent aorta was placed in tryptic soy broth, ultrasonically oscillated at 20 kHz for ten minutes to mechanically disrupt the prosthetic surface biofilm, and incubated at 35°C, a technique previously shown to increase the recovery of bacteria from explanted vascular prostheses compared with broth culture alone.[11] One graft-to-artery anastomosis was used for measurement of anastomotic tensile strength, while the other anastomotic site was used for histologic and microbiologic studies. One-centimeter lengths of aorta (suture line included) were cultured in tryptic soy broth at 35°C and fixed in 2% glutaraldehyde for hematoxylin-eosin and Brown-Brenn tissue Gram's staining for histologic examination. Aorta wall histologic findings were interpreted by a pathologist in a blinded fashion.

Following total graft excision, the aorta was débrided to grossly normal artery wall, and aortic continuity was established by implantation (randomized) of double-velour Dacron or PTFE grafts in study animals to undergo reoperation after five weeks and only PTFE grafts in study animals reexamined 12 weeks after in situ replacement. All animals underwent graft replacement using similar graft-to-artery anastomotic technique with a 6-0 continuous polypropylene suture. The perigraft cavity surround-

ing primary infected Dacron grafts was débrided to adjacent retroperitoneal structures (duodenum and inferior vena cava). The replacement graft was covered with retroperitoneum and the midline incision closed.

Explantation of Replacement Grafts

Five and 12 weeks after in situ replacement of the established *S epidermidis* graft infection, the aortic grafts were exposed through the prior midline incision. No antibiotic was administered prior to or during the operation. The extent of replacement graft healing was noted, including the presence or absence of graft incorporation, perigraft cavity, and fluid. The grafts were totally excised, including the adjacent aorta, without disruption of anastomotic sites and surrounding fibrous tissue. The replacement graft and adjacent aorta were analyzed, using tensiometer, microbiologic, and histologic methods previously described, to assess anastomotic tensile strength and determine whether recurrent *S epidermidis* colonization had occurred.

Measurement of Anastomotic Tensile Strength

Tensile strength of intact graft-to-artery anastomoses was measured with a linear gain tensiometer calibrated to 22.5 kg full scale using an elongation speed of 0.25 cm/s. Anastomotic sites were mounted with the perigraft capsule intact and held within the testing apparatus over a specially designed mounting device with 21-gauge wire to avoid slippage of tissue (Figure). Tensiometer reading was recorded continuously until disruption of the anastomosis occurred, at which time peak tensile strength (measured in kilograms) was determined. Peak tensile strength was recorded for each anastomosis and analyzed according to graft type, presence of clinical signs of graft infection, results of graft cultures, and time of implantation.

Data Analysis

All cultures without growth after 14 days were considered sterile. Bacterial isolates were identified and staphylococcal species isolated with the API STAPH-IDENT system. *Staphylococcus epidermidis* isolates were evaluated for slime production to verify recovery of the study strain. Anastomotic tensile strength difference between groups was expressed as the mean ± SEM. To avoid assumptions about the distribution of the tensiometry data, statistical significance was assessed by the Mann-Whitney U test.

RESULTS

All animals survived the operative procedures and follow-up intervals. One PTFE replacement graft was thrombosed at the time of excision, 12 weeks after implantation. No pseudoaneurysms or anastomotic disruptions were observed in the sterile control and primary infected Dacron grafts.

Vascular Prosthesis Biofilm Infection

Five weeks after implantation of Dacron grafts colonized in vitro with the study strain of bacteria, all study animals had patent grafts with microbiologic and anatomic evidence of *S epidermidis* infection (Table 1). An inflammatory process was present in the retroperitoneum, surrounding the prosthetic graft, and involving adjacent structures (aorta, inferior vena cava, duodenum). A perigraft cavity containing fibrinopurulent exudate was present in 17 (89%) of 19 dogs. Histologic examination of the aorta adjacent to suture lines demonstrated acute inflammation (wall thickening and multiple foci of polymorphonuclear leukocytes) in nine (47%) of 19 animals. By 1 cm from the anastomosis, the artery wall was normal. Sterile, control Dacron grafts implanted five weeks prior had no anatomic signs of infection, graft cultures yielded no growth, and aortic histologic examination demonstrated only foreign-body reaction (infiltrates of giant cells and histocytes) adjacent to suture material.

The anastomotic tensile strength of infected Dacron grafts was significantly less ($P<.003$) than control Dacron grafts (Table 2). For all anastomoses tested, disruption occurred at the suture line in the aorta. The peak tensile force required to disrupt the graft-to-artery anastomosis in animals with infected grafts and aortitis at the opposite anastomotic site (4.5 ± 1.6 kg) was less but not statistically different from that of anastomotic sites without adjacent aortitis (6.4 ± 1.4 kg).

Results of Graft Replacement

In situ graft replacement resulted in perigraft healing without signs of infection in 16 (89%) of 18 study animals (Table 1). Two Dacron grafts explanted after five weeks were poorly incorporated with a perigraft cavity present, and one PTFE graft at 12 weeks demonstrated pseudoaneurysm formation at the distal anastomosis. Of note, culture of the artery wall adjacent to the disrupted anastomosis isolated the *S epidermidis* study strain, but culture of the PTFE graft yielded no bacterial growth, and the peak tensile force required to disrupt the opposite anastomosis was 12.2 kg. All replacement PTFE grafts at five weeks after implantation showed no anatomic signs of infection, were adherent to perigraft tissues, and required scalpel dissection for excision. *Staphylococcus epidermidis* was recovered from two (11%) of 18 replacement grafts. Positive cultures for the study strain were obtained from the two Dacron replacement grafts that demonstrated no graft incorporation. Tensile strengths of anastomoses from these grafts were 9.5 and 14.4 kg, respectively.

Anastomotic tensile strength of replacement grafts was similar to that of control Dacron grafts and significantly increased compared with Dacron grafts infected with *S epidermidis*. Anastomotic tensile strength of Dacron and PTFE replacement grafts was similar, and duration following in situ replacement did not influence PTFE anastomotic bonding.

COMMENT

Our study confirmed that *S epidermidis* colonization of a vascular prostheses as a bacterial biofilm can incite a perigraft inflammatory process that involves the adjacent artery wall and decreases anastomotic tensile strength. Although anastomotic dehiscence was not observed in the primary infected Dacron grafts, the absence of this complication was likely because of the short (five-week) duration of graft implantation. The cause of anastomotic aneurysms has largely been attributed to host vessel degeneration due to abnormal mechanical stress at the suture line, but the possibility that a low-grade infection contributes to these disruptive forces has not been fully explored. Using a sensitive microbiologic culture technique, we have previously documented that microorganisms can frequently be isolated from vascular prostheses that require revision for complications of thrombosis or anastomotic pseudoaneurysm.[8] *Staphylococcus epidermidis* was the prevalent organism recovered (69% of

isolates), and slime production, a growth characteristic associated with prosthetic device infection in humans, was seen in 87% of strains isolated from grafts revised for anastomotic pseudoaneurysm. The canine model used in this study mimicked the anatomic and microbiologic characteristics of late graft infection in humans. Viable microorganisms were sequestered primarily within a biofilm on the prosthetic surface, and bacterial invasion of perigraft tissue and signs of graft sepsis were absent. Despite the localized nature of the infection and low virulence of the infecting *S epidermidis* organisms, graft colonization was recognized by host defenses, and a perigraft inflammatory process developed. If the artery wall adjacent to suture lines was involved either by inflammation and/or bacterial infection, anastomotic tensile strength was significantly less than the normal anastomotic bonding strength measured in grafts without clinical signs of infection. Of note, this canine model of *S epidermidis* graft infection demonstrated that the presence of arteritis adjacent to the suture line of grafts exhibiting clinical signs of infection was sporadic, occurring at one half (nine of 19) of anastomotic sites. When arteritis was documented, artery wall cultures yielded the *S epidermidis* study strain and anastomotic strength was significantly decreased. In only one animal was anastomotic dehiscence observed. These findings emphasize the importance of aortitis and artery wall infection as causes of aortic stump dehiscence following excision of an infected graft and as sources of infection of in situ replacement grafts.

The artery wall has been documented as a potential source for graft colonization and was in this study the likely origin of the PTFE replacement graft infection observed after 12 weeks of implantation.[7] Infection was manifest at an anastomotic site that previously demonstrated aortitis adjacent to an infected Dacron graft. Of importance, the PTFE graft exhibited no other signs of infection and the opposite anastomotic site had a normal tensile strength (12.2 kg). This observation suggests that infection of an in situ replacement graft may begin as an isolated process involving a single anastomotic site or segment of the prosthetic conduit. The decreased anastomotic tensile strength of grafts exhibiting perigraft inflammation is suggestive evidence that this process, if unabated, will eventually lead to anastomotic dehiscence. In contrast, the presence of normal anastomotic bonding (normal tensile strength and suture line histologic structure) following primary or in situ replacement is persuasive evidence that a suture line complication is unlikely to develop. Routine use of broth media for culture of vascular prostheses associated with anastomotic pseudoaneurysm and increased attention to the histologic structure of the artery wall adjacent to the prosthesis are required, if our understanding of this healing complication is to improve.

We have previously reported that in situ replacement of a graft with established *S epidermidis* infection resulted in graft healing without signs of infection.[9] The present study provides additional data that support the efficacy of in situ replacement for this infection. Graft healing was observed for three months after replacement and associated with normal anastomotic tensile strength. Persistent colonization was confirmed in only two (11%) of 18 replacement grafts, which was less than the one-third incidence observed after four weeks in a prior study.[9] The lower incidence of replacement graft colonization may have resulted from extended administration of antibiotics (ten days vs one day) following graft replacement, or the longer implantation time with resultant additional graft healing in animals with intact host defenses.

Anastomotic tensile strength was similar in PTFE and Dacron replacement grafts after five weeks and did not change in PTFE grafts implanted for 12 weeks. The tensile strength of graft-to-artery anastomoses measured in both control and replacement grafts was comparable with that measured by Quinones-Baldrich et al[10] in a similar canine model. The excellent perigraft healing and the low incidence of *S epidermidis* colonization of PTFE replacement grafts compared with Dacron grafts favor this prosthesis for in situ replacement of *S epidermidis* graft infections.

The diagnosis of graft infection caused by bacterial biofilms can frequently be made based on clinical presentation. Gram's stain of perigraft exudate typically demonstrates only polymorphonuclear leukocytes, and perigraft tissue culture is sterile. In contrast, infections caused by *Staphylococcus aureus* and gram-negative microorganisms are not confined to a surface biofilm but rather are associated with invasive infection of perigraft tissues and sepsis. In situ graft replacement should not be considered as a treatment option when Gram's stain shows microorganisms in the perigraft tissue/exudate, a manifestation of an invasive bacterial infection. When in situ graft replacement is utilized, the artery adjacent to the graft should be débrided to grossly normal wall. This procedure removes artery tissue weakened by arteritis and potentially colonized by *S epidermidis*, a source for graft reinfection. Antibiotics should be administered prior to and following in situ replacement to minimize bacterial adherence to and colonization of prosthetic surfaces, and to eradicate residual foci of bacterial arteritis.

Although our study demonstrates that normal anastomotic tensile strength is present three months following in situ replacement of aortic grafts infected with *S epidermidis*, late anastomotic complications may still develop. In situ replacement for *S epidermidis* graft infection mandates extended postoperative surveillance using anatomic diagnostic techniques, such as computed tomography, magnetic resonance imaging, or B-mode ultrasound capable of assessing perigraft healing and anastomotic integrity.

Hemodynamic Effects on Endothelial Cell Monolayer Detachment From Vascular Prostheses

Howard P. Greisler, MD; Eric D. Endean, MD; John J. Klosak, MD; Joan Ellinger; Scott C. Henderson; Si M. Pham, MD; Steven J. Durham, MD; David P. Showalter, MD; Jeffery Levine, PhD; Harvey S. Borovetz, PhD

• The establishment of an early blood-contacting endothelialized surface may improve the graft-host relationship. This study evaluated the adherence of indium 111–radiolabeled endothelial cells that were cultured to confluence on fibronectin-treated polyester elastomer (Hytrel) grafts that were perfused for two hours on a pulse duplicator apparatus under high- and low-shear conditions. Perfusate samples were serially assayed for radioactivity. After perfusion, grafts were sectioned into four segments and assayed for retained radioactivity. All graft segments were hematoxylin stained and examined under light microscopy for evaluation of cell density. Excellent endothelial cell adherence (90%) was observed under both hemodynamic conditions at 120 minutes, with most losses occurring within the first 15 minutes. No differences were seen between high- and low-shear conditions or proximal vs distal graft segments.

(*Arch Surg* 1989;124:429-433)

The need for improved small-diameter vascular prostheses has led to intense research on methods of optimizing the graft-host relationship. One suggested method of improving this relationship and optimizing the clinical efficacy of implanted grafts is the establishment of an early confluent endothelialized blood-contacting surface. The underlying assumption is that such an endothelialized surface would function to improve surface thrombogenicity and potentially inhibit subendothelial proliferative activity of fibroblasts and smooth-muscle cells and thereby decrease occlusions secondary to thrombosis and pseudointimal hyperplasia. Approaches to early endothelialization have included techniques for endothelial seeding,[1-5] the use of partially or totally bioresorbable grafts,[6-10] and the in vitro culturing of an endothelial cell monolayer on the prosthetic surface before implantation.[11] Investigations of endothelial cell attachment to treated and untreated prosthetic surfaces and resistance of this cell layer to detachment from the surface in circulation have yielded disparate results. A recent publication showed the loss of 30% of seeded cells after 30 minutes of perfusion and the loss of 83% of the cells after 24 hours,[12] while another recent study showed greater than 90% retention of endothelial cells cultured on either fibronectin-treated or collagen IV–III–treated polymer surfaces after 30 minutes of 90-dynes/cm^2 shear stress.[13] Optimization of endothelial cell adherence to the surface and preservation of normal endothelial cell functional characteristics are critical to the development of clinically efficacious endothelialized prosthetic surfaces. The current study evaluates the adherence of endothelial cells that were cultured on fibronectin-treated prosthetic materials that were perfused in vitro under different pulsatile hemodynamic conditions.

MATERIALS AND METHODS

A single mongrel dog was anesthetized with intravenous thiamylal sodium and anesthesia was maintained with 0.8% methoxyflurane, 30% nitrous oxide, and 69.2% oxygen. Under sterile conditions, both external jugular veins were removed, carefully everted, and placed in Hanks' balanced salt solution (calcium and magnesium free). The veins were then placed in trypsin (0.05%)–edetic acid (EDTA) (0.02%) (pH, 8.0) and incubated at 37°C for ten minutes. The veins were removed and placed in 40 mL of collagenase (0.05%) (pH 7.0) and incubated for an additional ten minutes. The veins were then discarded, and the cell-containing enzyme solutions were centrifuged for ten minutes at 800 revolutions per minute. The cell pellets were reconstituted in complete media that contained M-199 culture media, 10% fetal bovine serum, beef lung heparin sodium (5 U/mL), and purified endothelial cell growth factor (5 ng/mL). Endothelial cell purity was documented by immunoperoxidase stains (Fig 1) with rabbit anti–human factor VIII antibody (DAKO Corp, Santa Barbara, Calif) and a goat anti–rabbit secondary antibody (Vector Laboratories, Burlingame, Calif). The cells were seeded in T-25 tissue culture flasks

that were previously coated with fibronectin (10 μg/cm²). The cells were incubated at 37°C in a 5% carbon dioxide–humidified atmosphere. Culture media were changed every other day. When confluence was achieved, the cells were serially passaged three times, yielding 25 confluent T-75 flasks. The cells were then enzymatically removed and resuspended in phosphate-buffered saline, and cell counts were performed on both a Coulter counter and a hemacytometer. Oxine (100 μCi per million cells), labeled with indium 111, was added and incubated for 30 minutes at 22°C, followed by centrifugation at 1000 revolutions per minute for ten minutes. Phosphate-buffered saline washing was repeated three times to remove unattached ^{111}In. The final cell pellet was reconstituted in complete media in a volume four times that calculated to fill the grafts.

The grafts, 80 × 4 mm internal diameter, were composed of a polyester elastomer (Hytrel) that was translucent to light microscopy. The graft lumina were coated with fibronectin (0.01 mg/mL) before cell seeding. A stopper apparatus was fashioned on the ends of the grafts, and they were inoculated four times with the cell-containing media, with the total cell inoculum being 3.4×10^6 cells per square centimeter. The stoppers were then removed, and the endothelial cell–bearing grafts were placed in culture flasks that were submerged horizontally in complete media and incubated as previously described. They were rotated periodically to ensure circumferential coverage. The grafts were examined daily, and when confluence was visually achieved, the grafts were transported to a pulse-duplicating apparatus.

Endothelial cell-seeded grafts (Hytrel) were perfused in an in vitro perfusion circuit that was capable of simulating low-flow (30 to 300 mL/min) peripheral vascular hemodynamics. A computer-aided designed and machined disk cam and roller follower provided pulsatile pressure and flow waveforms at a frequency of 1 Hz.[14] In operation, the flow of perfusate (medium 199) passes through a prosthetic aortic valve and compliance chamber before entering the graft-housing chambers. Each housing chamber is filled with normothermic lactated Ringer's solution and contains one graft segment, along with various sensors (Fig 2). Hemodynamic parameters, measured at various locations within the housing chamber, include perfusion pressure, both proximal and distal to the graft segment (Mikro-Tip pressure transducers, model PC-360, Millar Instruments, Inc, Houston); fluid pressure (Millar Instruments Inc) within the housing chamber; and flow rate through the graft (model 501 flowmeter and model EP300A flow probe, Carolina Medical Electronics Inc, King, NC).[15] Fluid that exits the tissue chamber flows directly into a reservoir, thereby connecting the entire flow path in a closed loop.

The grafts were placed on the perfusion apparatus in pairs, and four runs were performed to perfuse all eight grafts. Before the runs, the distal 1-cm segments of each graft were excised to exclude the effect of the stoppers rubbing off cells, and 6 cm of each graft was exposed to the pulsatile-circulating media. Two hemodyamic conditions were established, and both grafts of each pair were subjected to one or the other condition. In one condition, each graft was subjected to pressures of 120/80 mm Hg and a mean flow of 90 mL/min with a shear rate of 240 inverse s. The alternate perfusion condition was 200/100 mm Hg and a mean flow of 195 mL/min with a shear rate of 520 inverse s. Shear rates were calculated according to Poiseuille's law. The grafts were maintained on the perfusion apparatus for 120 minutes. Periodic samples of the perfusate were obtained to ensure physiologic gases. Samples of perfusate were obtained at 5, 15, 60, and 120 minutes for radioactivity determination, representing ^{111}In shed during per-

fusion. At the end of the 120 minutes, the grafts were removed from the perfusion apparatus and sectioned proximally to distally into the central four 1-cm segments, with the two end 1-cm segments being discarded to avoid artifact. Each segment was then placed into complete media and assayed for residual radioactivity. The specimens were then fixed in 40% formaldehyde solution and stained with Gill's hematoxylin for photography and evaluation of retained cell density. Three blinded experienced observers independently evaluated the grafts under light microscopy to determine the cell density on a qualitative scale, with 4+ as confluent, 3+ as nearly so, 2+ as nonconfluent, and 1+ as scattered cells.

RESULTS

Figure 3 illustrates the activity of the perfusate vs time during the two low-flow/pressure runs. All four grafts (perfused in pairs) were utilized to generate these two curves. These bimodal curves demonstrate a relatively rapid initial rise in activity, indicating that most of the radioactivity cell loss occurred during the first 15 minutes. The slope of the curves then decreases substantially, becoming virtually asymptotic.

Figure 4 illustrates the activity of the perfusate vs time during the two high-flow/pressure runs. Again, four grafts (perfused in pairs) were utilized. Curves similar to those of Fig 3 were generated, revealing a relatively rapid initial loss of radioactivity with minimal loss thereafter.

Following perfusion, each 1-cm segment was assayed for residual radioactivity. The results are illustrated in Fig 5, which represents the four 1-cm segments of the grafts from proximal to distal. The residual radioactivity of each graft segment is shown under the schematic of its relative position along the length of the graft. There is no significant

Fig 5.—Counts per minute (cpm) of postperfusion graft segments for each of eight grafts, arranged proximally to distally in respect to perfusate flow. Mean ± SD for each segment position is shown for both flow conditions.

Fig 6.—Mean cell density scores of postperfusion Gill's hematoxylin–stained graft segments, determined by three blinded observers using light microscopy, with scores as follows: 4.0, confluent; 3.0, nearly so; 2.0, not confluent; and 1.0, scattered cells.

Fig 7.—Representative photomicrograph of Gill's hematoxylin–stained segment after high-flow/pressure graft. Hematoxylin stains only nucleus, with cytoplasm making up most of nonstained area (×10).

difference in retained radioactivity between the high- and the low-flow/pressure conditions.

Histologic evaluation of retained cell density is depicted in Fig 6, showing the mean scores given by the three blinded observers. A representative photomicrograph of a Gill's hematoxylin-stained segment following two hours of perfusion is shown in Fig 7. Gill's hematoxylin stains only the nucleus, with the cytoplasm occupying much of the remaining space. The blurred margins of the photomicrograph simply reflect focusing difficulty due to the convex nature of the specimen. The majority of the graft segments were considered to be near-confluent. Again, no significant differences are seen between the hemodynamic conditions or between graft segments.

The percentage of shed radioactivity during perfusion can be determined by calculating the radioactivity present on the grafts initially and comparing this with the residual activity on the grafts after each run. The initial activity could not be measured before perfusion directly because of the size of the graft, so the initial activity was calculated by summing the individual activity of the eight graft segments of each run and adding to this the total activity present in the perfusate at the end of each run. The activity present in the perfusate was calculated by multiplying the total volume in milliliters by the activity in counts per minute per milliliter of perfusate at 120 minutes. The calculated percent loss of endothelial cells (radioactivity) from the grafts during 120 minutes of perfusion of two grafts in both hemodynamic/pressure conditions was as follows: high flow: run 2, 10.2%, and run 3, 7.9%; low flow: run 1, 11.1%, and run 4, 9.5%. The percent loss is never greater than 12% of the initial radioactivity, which is consistent with the qualitative data illustrated in Fig 6 of retention of the endothelial cell monolayer at near-confluent levels.

COMMENT

The current enthusiasm for enhancing clinical efficacy of small-diameter vascular grafts by an early establishment of a confluent, functioning endothelialized blood-contacting surface, either through endothelial cell transplantation or through endothelial cell culture onto prosthetic surfaces, rests on the hopes that endothelial cells will both resist detachment under physiologic hemodynamic conditions and will function in a capacity, such that their procoagulant/anticoagulant and mesenchymal cell growth–regulating potentials are optimized. The adherence of an endothelial monolayer to a surface is dependent on the physical and biochemical characteristics of that surface. Studies attempting to optimize cell-surface attachment surface characteristics are currently under way in several laboratories. Recent studies of the effects of flow on cell detachment have yielded disparate results. The current study examines the effects of hemodynamics at the two extremes of physiologic conditions on cell adherence to fibronectin-coated polyester elastomer surfaces.

The results, whether measured quantitatively as retained radioactivity or semiquantitatively as retained cell numbers, show a remarkable retention of endothelial cells cultured on the material surface. No significant differences were found between high- and low-shear conditions. Essentially 90% of the initial confluent monolayer remained attached to the prosthetic surface following the two-hour perfusion. These results are consistent with the recent study by Schneider et al[16] in which 94% of endothelial cells remained adherent to a small-caliber prosthesis at one hour with flows of 100 mL/min. Our data further suggest that essentially no cell loss occurs following the initial 15 minutes of perfusion under these experimental conditions.

Previous work from our laboratory[17] in which endothelial cells were cultured on fibronectin-treated expanded polytef prostheses demonstrated a similar lack of effect of hemodynamics on percent cell loss but did demonstrate a shift of cell density from proximal to distal, interpreted as migration of cells in the direction of flow, intensified in the high-flow condition. This was not seen in the current study with polyester elastomer. An explanation for this discrep-

ancy may be a difference in cell attachment forces to the two prosthetic materials. However, several methodologic differences were used in these two studies, and the former (expanded polytef) study requires confirmation to rule out methodologic reasons for the different results.

More important than documentation of cell retention by a prosthetic surface under physiologic hemodynamic conditions is the documentation of favorable endothelial cell functional characteristics. For example, Frangos and colleagues[18] reported augmentation of endothelial cell prostacyclin production in response to pulsatile flow conditions in culture. Sumpio et al[19] have reported augmented rates of endothelial cell proliferation in response to cyclic deformation, and quite likely, other mechanical stimuli and hemodynamic parameters can affect a wide variety of endothelial cell functional characteristics. Any alteration from normal cell–cycling behavior likely yields a modification of cellular synthetic activity of any of a large number of endothelial cell–derived effector substances. Much work is needed to evaluate endothelial cell function on different prosthetic surfaces in response to both hemodynamic conditions and cell-material interactions.

The results of this study confirm that canine jugular vein endothelial cells, grown to confluence on fibronectin-coated polyester elastomer small-diameter vascular prostheses, will be retained at 90% confluence by that surface following two hours of perfusion under the two extremes of physiologic hemodynamic parameters.

The Costs of Employee Smoking: A Computer Simulation of Hospital Nurses

Robert T. Swank, MA; Diane M. Becker, ScD, MPH; Catherine A. Jackson, MS

A computer simulation model of the economic impact of employee smoking on an employer was developed with a population of hospital nurses as the example. Net economic impact was calculated by estimating cumulative costs borne by the employer under various scenarios and comparing them with projected costs estimated from baseline data. The model included the following: baseline number of staff, baseline percentage of smokers, annual employee turnover rate, number of smokers interested in quitting, the cost of a smoking cessation program, expected success rate of a voluntary cessation program, smokers quitting spontaneously without a program, and employer-borne costs related to employee smoking. A variety of scenarios were constructed to generate a range of employer net economic impact figures and resulting percentages of smoking employees. Results showed that the benefits of a cessation program would be eliminated over several years, unless the prevalence of smoking in incoming employees was reduced. The most favorable scenario, combining a hospital cessation program and reduced smoking among new employees, generated cumulative savings, discounted at 5%, of $358 000 to $684 000 over an eight-year period (*Arch Intern Med* 1988;148:445-448).

Pentoxifylline Increases Extremity Blood Flow in Diabetic Atherosclerotic Patients

Richard W. Schwartz, MD; Nancy M. Logan; Paul J. Johnson, MD; William E. Strodel, MD; Joseph G. Fine, MD; Andris Kazmers, MD; Gordon L. Hyde, MD

• Pentoxifylline, a new trisubstituted methylxanthine derivative known for its hemorrheologic action, has been shown to improve exercise tolerance in atherosclerotic patients. We examined the response of diabetic atherosclerotic patients to pentoxifylline administration, measured by Doppler waveform analysis and exercise tolerance. Standard exercise tolerance and Doppler waveform analytic studies of the lower extremity, specifically the right dorsalis pedis artery, were performed before and after three months of pentoxifylline administration (400 mg three times a day). The study group comprised ten subjects (six men and four women) with a mean (±SD) age of 60±3.3 years. Data were analyzed using a paired Student *t* test. All ten subjects showed a significant increase in exercise tolerance after pentoxifylline treatment. Eight of ten subjects demonstrated a significant increase in right dorsalis pedis arterial flow.

(*Arch Surg* 1989;124:434-437)

A number of blood flow characteristics are reported to be altered in chronic arterial disorders such as atherosclerosis and diabetes mellitus, including increased blood plasma viscosity, decreased red blood cell deformability, increased fibrinogen level, decreased fibrinolytic activity, platelet hyperactivity, and plasma hypercoagulability.[1-9] Numerous investigators[10-16] have documented improvement in some or all of these pathophysiologic flow abnormalities in patients with both atherosclerosis and diabetes, following the administration of pentoxifylline (Trental). Pentoxifylline has also been shown to induce vasodilatation in the rabbit hindlimb[17] and to exert relaxing effects on vascular smooth muscle.[18] These reported improvements in hemorrheologic flow characteristics should decrease peripheral vascular resistance and theoretically result in an increased peripheral tissue blood flow. Because of these positive hemorrheologic effects, pentoxifylline has been commonly prescribed in Europe and North America for the treatment of chronic occlusive arterial disease (COAD).

In the past decade, Porter et al[19] and others[20-24] have demonstrated the clinical efficacy of pentoxifylline in improving both initial claudication distance and absolute claudication distance in atherosclerotic patients with claudication. In the study conducted by Porter et al, these distances increased by as much as 100% in one third of the subjects taking pentoxifylline.

Not all investigators, however, have been able to show that pentoxifylline greatly improves either claudication distance or hemorrheologic characteristics in patients with intermittent claudication,[25] so it is clear that many questions about the usefulness of the drug remain unanswered. One weakness in the measurement of initial claudication distance is that it is somewhat subjective, because the investigator must rely on the subjects' signal at the onset of claudication. Total exercise time is less subjective, simply because the subjects walk until they cannot walk farther. It should be noted that Porter et al[19] attributed 50% of the improvement in claudication distances to placebo effect.

Given this lack of objective clinical evidence of improved blood flow following pentoxifylline therapy, the purpose of this study was to determine whether circulatory changes due to pentoxifylline administration could be assessed quantitatively via Doppler waveform analysis.

SUBJECTS AND METHODS

Subjects

Ten subjects (six men and four women) with a mean (±SD) age of 60±3.3 years were studied. The entry criteria included the following: (1) severe COAD as determined by physical assessment (eg, absence of or diminished peripheral pulses on palpation, minor trophic skin changes, elevation pallor of the lower limbs, and dependent rubor) and the results of noninvasive vascular testing (monophasic or biphasic Doppler waveforms and ankle/brachial [A/B] indexes <0.8); (2) intermittent claudication that had been stable for at least six months; (3) the ability to walk at least 20 m, but not farther than 200 m, on a treadmill before experiencing claudication; and (4) diabetes mellitus as defined by World Health Organization criteria, ie, fasting venous plasma glucose concentration greater than 7.8 mmol/L on at least two occasions, or a positive oral glucose tolerance test.

Criteria for initial exclusion included the following: (1) severe COAD as manifested by rest pain, lower-extremity ulcers, or

Fig 1.—Mean exercise tolerance before (solid bar) and after (open bar) pentoxifylline therapy.

Fig 2.—Mean dorsalis pedis blood flow before (solid bar) and after (open bar) pentoxifylline therapy.

gangrene; (2) lumbar sympathectomy within the previous three months; (3) lower limb amputation; (4) serious concomitant cardiac, pulmonary, or malignant disease; (5) hypersensitivity to methylxanthine agents; and (6) previous use of pentoxifylline.

Study Design

Each subject participated in this study for a total of 16 weeks. The first four weeks constituted a "washout" phase, during which all medications (eg, vasodilators) being taken to treat intermittent claudication were discontinued. Pentoxifylline was not prescribed during this phase of the study. The purpose of the first phase was to verify the stability of the degree of intermittent claudication, which allowed each subject to serve as his/her own control, and to familiarize the patients with treadmill procedures.

At the start of the first phase (visit 1), each subject underwent a complete physical examination and electrocardiography. Lower-extremity vascular examination included Doppler waveform measurements at rest, and arterial pressures measured both at rest and after treadmill exercise. The Doppler equipment (Narcolab Arterial Diagnostic Unit, Narco Scientific Diagnostic Division, Huntington Valley, Pa) had an 8-mHz probe. To achieve the best Doppler measurement, the probe was tilted against the skin at an angle allowing the clearest audio signal (45°). Three experienced vascular technicians were trained for this study, although the data presented herein were collected, with few exceptions, by the same technician. The treadmill (Model 16-50, Quinton Instruments, Seattle, Wash) was set at a constant speed of 2.5 km/h and at a 12% grade.

During treadmill exercise, both the time interval to the onset of claudication and the total time that the subject was able to walk (total exercise time) were recorded. Symptoms accepted as representing claudication included lower-extremity pain, aches, cramps, and severe fatigue.

At the end of the washout phase (visit 2), the treadmill measurements were repeated. If the time interval to the onset of claudication measured at visits 1 and 2 differed by more than 20%, the subject was excluded from the study.

At this point, eligible subjects were then entered into the treatment phase of the study and were prescribed pentoxifylline (400 mg three times a day) for the remaining 12 weeks. To ensure that changes in exercise tolerance were due to pentoxifylline alone, subjects were instructed not to alter their smoking or exercise habits for the duration of the study. During the treatment phase, subjects were evaluated on four occasions (weeks 2, 4, 8, and 12). At each of these visits, they were monitored for concomitant medications, side effects, and health changes. The vascular examination at these visits included physical assessment, calculation of resting A/B indexes, measurements of the time interval to claudication, and the total exercise time. At the final visit (week 12), Doppler waveform measurements were also obtained.

Data Analysis

The response to treatment with pentoxifylline was assessed by changes in total exercise time (in seconds), A/B indexes, and Doppler waveforms. All lower-extremity arteries were analyzed qualitatively. Quantitative changes in Doppler waveforms of the dorsalis pedis artery were determined by calculating the area under each waveform curve using a computer (Systems III, Cromenco, Mountain View, Calif)/digitizer (Talos Systems Inc, Scottsdale, Ariz). The magnitude of the arterial flow pulse (technically referred to as the arterial blood bolus) from systole to systole was measured by calculating the integral area (in centimeters) under each waveform (the product of the y axis equals centimeters per second, and the x axis equals seconds). This is representative of the blood volume per heartbeat in the dorsalis pedis artery. The quantitative data were analyzed statistically using Student's t test. Significance was defined as $P<.05$.

RESULTS

Exercise Tolerance

Mean ($\pm$SE) exercise tolerance increased significantly from 140 ± 20 s to 256 ± 20 s following pentoxifylline administration ($P<.001$). This represented a mean increase of $101\% \pm 67\%$ (Fig 1).

A/B Indexes

There was no significant change in dorsalis pedis pressure measurement following treatment. The mean initial dorsalis pedis arterial A/B index was 0.58 ± 0.21; the mean posttreatment index was 0.60 ± 0.15.

Doppler Waveforms

Nine of the ten subjects demonstrated improvement in waveforms after three months of treatment. Six of the subjects had a mean increase of $82\% \pm 57\%$ in the magnitude of their dorsalis pedis waveform area measurements. Two subjects had no measurable dorsalis pedis signal before treatment but developed measurable signals following treatment. These eight subjects significantly ($P<.01$) increased their mean dorsalis pedis waveform from 206 ± 74 cm to 372 ± 85 cm (Fig 2). One subject increased his waveform tracing to such a point that it was consistently off the graph paper and subsequently could not be analyzed with the computer/digitizer. One subject demonstrated a decrease in waveform at the dorsalis pedis artery; she admitted being marginally compliant with the pentoxifylline regimen. Figure 3 demonstrates actual waveforms before and after three months of treatment in a subject who had demonstrated a measurable signal before treatment. Figure 4 shows the waveforms in a subject who had not had a measurable signal before treatment.

COMMENT

Pentoxifylline, a trisubstituted methylxanthine derivative, is the most well known of a new group of hemorrheo-

Fig 3.—Waveforms of one subject's left dorsalis pedis artery flow before (left) and after (right) three months of pentoxifylline therapy.

Fig 4.—Doppler waveforms from one subject's left dorsalis pedis artery before (left) and after (right) three months of pentoxifylline therapy. Doppler signal in this artery was inaudible before subject's participation in study.

logic agents. Several investigators[10-16] have shown that pentoxifylline therapy improves hemorrheologic abnormalities associated with diabetes and atherosclerosis. However, reports in the literature about the clinical improvement in patients taking pentoxifylline for the treatment of intermittent claudication have been contradictory.[19,21,23-25] To our knowledge, no studies have shown clear evidence that the use of this agent leads to improvement in distal extremity arterial flow as measured by noninvasive vascular tests.

The data presented in our pilot study demonstrate a mean 100% increase in claudication time. These findings are consistent with other reports in the literature.[19,21] The unique feature of this report is the significant ($P<.01$) change seen in the distal extremity arterial Doppler waveforms in seven subjects, and the reestablishment of dorsalis pedis flow in two subjects as measured by the digitizer method. This type of analysis calculates the area under the waveform curve (y axis equals centimeters per second, and x axis equals seconds). The actual measurement obtained is the length of blood bolus per heartbeat (measured in centimeters). Although only the dorsalis pedis artery waveforms were analyzed quantitatively by the digitizer method, each subject showed marked qualitative improvement in waveforms of other distal extremity arteries. The only subject who failed to demonstrate improvement on Doppler waveform testing was one who had poor compliance with the medication regimen. For the remaining subjects, although the waveform testing demonstrated marked improvement, A/B pressure indexes remained relatively unchanged. This latter finding was similar to the results found by other investigators.[26,27]

Our results may be explained by several independent mechanisms. First, clinical experience has shown that arterial waveforms may be a more sensitive indicator of changes in arterial flow than the A/B index.[26,27] Second, A/B indexes in diabetic patients are often unreliable, especially if COAD with significant arterial calcification exists. Third, since pressure is the product of flow and resistance (pressure equals flow times resistance), blood flow should increase if resistance decreases and arterial pressure remains stable. Pentoxifylline therapy may decrease resistance inherent to both COAD and diabetes by inducing vasodilatation and/or by improving the hemorrheologic disturbances. Diabetic patients with coexistent atherosclerosis might be particularly susceptible to the hemorrheologic effects of pentoxifylline, since this group may well have hemorrheologic abnormalities that are worse than those for either disease entity alone.

Our results demonstrate that the magnitude of the flow pulse (technically referred to as a blood bolus) in the dorsalis pedis artery from systole to systole is significantly increased. This measurement is representative of the increase in blood volume per heartbeat in the dorsalis pedis artery following pentoxifylline treatment.

In conclusion, pentoxifylline has been shown to produce variable amelioration of the hemorrheologic pathophysiologic problems associated with both atherosclerosis and diabetes mellitus. Both relaxation of smooth muscle and vasodilatation have been demonstrated in animal studies.

The exact mechanism by which pentoxifylline exerts its positive hemorrheologic effects in either the macrocirculation or the microcirculation has yet to be determined. However, the improvement in dorsalis pedis arterial flow demonstrated by this pilot study indicates that a randomized trial of pentoxifylline treatment may be appropriate in the diabetic atherosclerotic patient group.

This study was funded by Hoechst-Roussel Pharmaceuticals Inc, Somerville, NJ.

Who Gets Screened for Cervical and Breast Cancer? Results From a New National Survey

Rodney A. Hayward, MD; Martin F. Shapiro, MD, PhD; Howard E. Freeman, PhD; Christopher R. Corey, MA

To evaluate the adequacy of cervical and breast cancer screening in the United States, data were analyzed from a 1986 nationwide telephone survey (n = 4659). Papanicolaou smears within the recommended three- to five-year interval were reported by 79% of women aged 20 years or older. Within the preceding year, 55% of women aged 40 years or older had breast examinations performed by physicians, and 20% of women aged 50 years or older had mammograms. Women who were uninsured or lower in socioeconomic status were less likely to have each of these three preventive measures, independent of the age, health status, and frequency of physician visits of the respondent. In addition, women aged 50 years or older were less likely to have had Papanicolaou smears (63% vs 89%) and breast examinations (52% vs 68%) than those women aged 20 to 49 years. These findings suggest that women who are older, uninsured, or lower in socioeconomic status are at an increased risk for not receiving preventive care, and that screening mammography, although more common than a decade ago, is still markedly underused (*Arch Intern Med* 1988;148:1177-1181).

Microvascular Free-Tissue Transfer

The Atlanta Veterans Administration Medical Center Experience

Grant W. Carlson, MD, John J. Coleman III, MD

• The entire microvascular tissue transfer experience from 1977 through 1987 at the Atlanta Veterans Administration Medical Center has been reviewed. Seventy-four free flaps were done in 68 patients. Assessable records were available in 52 patients who had 58 reconstructive procedures. The most frequently used flaps were jejunum in 15 patients (25.8%), latissimus dorsi in 11 patients (18.9%), rectus abdominis in eight patients (13.8%), and gracilis in seven patients (12.1%). Major complications occurred in 43.1% of the cases. Total flap loss occurred in eight patients (13.8%); from 1977 through 1982, four (28.6%) of 14 patients had total flap loss, and from 1983 through 1987, four (9.1%) had total flap loss. Partial flap loss occurred in four cases (6.9%). Of the 52 patients, 43 had their problems resolved expeditiously by free-tissue transfer. We conclude that in a university-affiliated Veterans Administration medical center, microvascular reconstruction is an important and necessary surgical tool. Failure rates have decreased markedly with time and increasing experience. Definition of new anatomic microvascular units for transfer has increased the number of reconstructive choices.

(*Arch Surg* 1989;124:438-440)

Microvascular tissue transplantation has undergone explosive growth and development since its reintroduction approximately 15 years ago.[1] Technical improvements in operating microscopes and an increased interest in cutaneous and muscular vascular anatomy led to a large number of new sources of tissue, some of which are easier to identify and more reliable than previous free flaps.

The advantages of free-tissue transfer are numerous. Many reconstructions can be done in one stage, eliminating costly multiple hospitalizations and operations. Consecutive procedures can be carried out with multiple flaps as required, without enlarging the local defect as is the danger with regional flaps. Free-tissue transfer minimizes the limitations of size and arc of rotation imposed by regional flaps. Distant donor sites allow greater flexibility in the design and transfer of composite tissue. The independent blood supply enables free flaps to be useful in compromised wounds over large avascular areas, such as bone or foreign body, and permits the vascular anastomosis to be performed outside the zone of injury or tumor involvement.[2]

In this study, the evolution of free-tissue transfer was examined from 1977 through 1987. Changing indications and results were reviewed with respect to the development of new types of free flaps.

PATIENTS AND METHODS

The entire microvascular tissue transfer experience from 1977 through 1987 at the Atlanta Veterans Administration Medical Center (VAMC) was reviewed. Seventy-four free flaps were done in 68 patients. Assessable records were available in 52 patients who had undergone 58 reconstructive procedures. Patient medical charts were reviewed to determine free-flap type, indications, results, complications, and long-term results. The review was divided into two time periods—1977 through 1982 and 1983 through 1987—to examine better the progression of free-tissue transfer.

The average age of patients was 51.3 years. There were 51 men and one woman. The majority of patients had underlying medical problems, including tobacco abuse in 28 patients, alcohol abuse in 16 patients, systemic arterial hypertension in nine patients, and atherosclerotic heart disease in seven patients.

RESULTS

As new techniques were developed and refined, the type of free flap and the indications varied in frequency. The most common flaps in 1977 through 1982 were latissimus dorsi in six patients (42.9%), jejunum in two patients (14.3%), and deep circumflex iliac artery (DCIA) osteomusculocutaneous flaps in two patients (14.3%). During 1982 through 1987, there was a change in distribution to the jejunum in 13 patients (29.5%), rectus abdominis in eight patients (18.2%), gracilis in seven patients (15.9%), radial forearm flap in five patients (11.4%), and latissimus dorsi in five patients (11.4%) (Fig 1). Over the entire decade, the most frequently used flaps were the jejunum in 15 patients (25.8%), latissimus dorsi in 11 patients (18.9%), rectus abdominis in eight patients (13.8%), and gracilis in seven patients (12.1%) (Fig 2). Complications occurred in 25 of 58 free-flap procedures (43.1%), including total free-flap loss in eight procedures (13.8%), partial flap loss in four procedures (6.9%), donor site problems in four patients (6.9%), and reexploration for hematoma or anastomotic problems in four procedures (6.9%). The total free-flap loss was 28.6% (4/14) during the first six years of the review but improved to 9.1% (4/44) during the second five-year period. One death (1.7%) occurred.

Donor site problems included three wound hematomas (5.2%) and one failed skin graft over the radial forearm donor site. Reexploration was performed in four cases, two of these for graft ischemia. Both grafts were salvaged with anastomotic revision. Wound hematomas were evacuated in two cases without jeopardy to the free flaps.

Orocutaneous fistulas occurred in three cases (5.2%) of jejunal free-flap reconstruction of the hypopharynx. Two fistulas closed spontaneously, and one required a sternocleidomastoid flap.

In the complex reconstructions that necessitate microvascular tissue transfer, an inadequate result can be secondary to some technical misadventure or to inappropriate use or expectations of the method. Three failures occurred in patients with large ventral hernias reconstructed with tensor fasciae latae free flaps. Recurrent herniation occurred in all three patients. Although it provides an ample amount of soft tissue, the tensor fasciae latae is probably not strong enough for definitive abdominal wall reconstruction above the umbilicus.

Numerous studies have demonstrated the ability of well-vascularized muscle to minimize the effects of bacterial colonization and improved wound healing in an otherwise unfavorable environment.[3,4] As our experience has increased, however, we have learned the limitations of the

muscle in the infected and ischemic extremity. In three extremity reconstructions, the repair was inadequate. One patient with a massive injury to the hip required disarticulation after a latissimus muscle flap, and repeated débridements failed to control sepsis in the wound. In two patients, osteomyelitis persisted despite adequate coverage, probably secondary to residual foreign body, sequestrum, or hardware.

Free flaps to the head and neck accounted for three operative failures. One failure was the result of a patient avulsing a radial forearm flap reconstruction of a traumatic facial defect. Another failure occurred after two attempts at jejunal flap reconstruction of the hypopharynx. The initial failure was the result of kinking of the artery. The cause of the second failure was unknown but was assumed to be of technical origin. The pectoralis major tube flap was constructed as a salvage procedure, which failed to function, and the patient died of aspiration. The third operative failure occurred in a patient who had a resection of a craniofacial tumor. A latissimus dorsi free-flap reconstruction failed because of poor arterial inflow resulting from extracranial cerebrovascular disease.

Anatomic discoveries and the availability of a greater number of versatile flaps resulted in the addition of more complex head and neck reconstructions to extremity coverage as an indication for free-tissue transfer. During 1977 through 1982, lower-extremity reconstruction required eight (57.1%) of 14 and head and neck reconstruction required six (42.9%) of 14 of the microvascular tissue transfers. The period 1983 through 1987 saw head and neck reconstruction become the major reason for free-tissue transfer. Free-tissue transfer made up 65.9% (29/44) of the total reconstruction, with extremity reconstruction falling to 27.3% (12/44). During 1983 through 1987, the tensor fasciae latae free flap was introduced for abdominal wall reconstruction and was used in three (6.8%) of 44 patients (Fig 3).

Composite free flaps of skin, muscle, and bone were a major part of reconstruction in seven cases (12.1%), including DCIA in three cases, free fibula in two cases, serratus osteomusculocutaneous flap in one case, and radial osteofasciocutaneous flap in one case. Osseous nonunion in two complex tibial fractures complicated by osteomyelitis was successfully resolved by contralateral vascularized fibula

Fig 2.—Fifty-eight free flaps at the Atlanta Veterans Administration Medical Center, 1977 through 1987.

transfer. After composite resection of the oral cavity (three cases) and trauma secondary to gunshot wound (one case), the mandible was reconstructed with good bony union and with soft-tissue lining provided with the DCIA flap (two cases), serratus osteomusculocutaneous flap (one case), and radial forearm osteofasciocutaneous flap (one case). A complex three-dimensional defect resulting from radical hemimaxillectomy was repaired with a DCIA flap.

COMMENT

The last decade has seen the rapid development of microvascular free-tissue transfer. Refinement in technique, recapitulation of the axial blood supply to muscle, and the discovery of new cutaneous vascular territories have expanded the usefulness of this modality. Our experience at the Atlanta VAMC parallels this evolution. From 1977 through 1982, lower-extremity reconstruction was the major indication for free-tissue transfer. The resurgence of the jejunal free flap, first described in 1959,[5] and the description of the radial forearm fasciocutaneous flap have made microvascular tissue transfer an important and reliable method in head and neck reconstruction. From 1983 through 1987, head and neck reconstruction became the major indication for free-tissue transfer.

Fig 3.—Indications for microvascular free-tissue transfer, 1977 through 1982 vs 1983 through 1987.

The flap failure rate for 1977 through 1982 was 28.6% but decreased to 9.1% during 1983 through 1987. The overall flap failure rate of 13.8% is similar to previous reports.[2,6,7] In this series, the type of free flap did not determine failure rate. Technical problems were identified in four (50%) of eight cases of flap loss (causes: one patient, arterial; two patients, venous; and one patient, unknown). Two of these patients were salvaged with a second free flap. Inadequacy of donor vessels resulted in three cases of flap loss (37.5%), two of which were attempts at limb salvage in severely ischemic extremities. Lack of patient compliance was the cause in one case.

Operative success can no longer be measured in free-flap survival. Success must now be defined as resolution of the serious wound or restoration of function—be it restoration of gastrointestinal tract continuity or treatment of osteomyelitis. The operative success of microvascular free-tissue transfer at the Atlanta VAMC was 82.7%; 43 of 52 patients had satisfactory resolution of their problem. Our retrospective study has shown that as experience with microvascular tissue transfer increases, both the technical failures and inappropriate indications decrease. Reconstructive problems indigenous to our VAMC have been chronic osteomyelitis, ischemic limb problems, and head and neck cancer resections. Other problems amenable to microvascular repair include hand and extremity trauma, facial reanimation, or penile reconstruction. Continued investigation and evaluation of functional results will improve our abilities to select the proper reconstructive method and employ it to the patient's best benefit.

There has been a steady increase in anatomic information concerning the vascular supply to muscle, skin, and bone over the last 15 years that has translated directly into useful reconstructive methods. Early work by Ger[8] and others on muscle flaps in the lower extremities stimulated interest that resulted in a codification of useful muscle and musculocutaneous units by Mathes and Nahai[9] and McCraw et al.[10] Although the initial approach has emphasized local transposition of tissue, it soon became apparent that these units could be transferred by microvascular technique to satisfy complicated distant tissue demands with minimal donor site morbidity. The obvious utility and efficiency of these methods led to further experimental and clinical endeavors resulting in composite osseomusculocutaneous flaps, such as those of the DCIA described by Taylor et al,[11] and the fibula. Ponten[12] and others provided better understanding of the previously described axial cutaneous flaps, such as the groin flap, with the elucidation of the fasciocutaneous vascular system and its subsequent contributions, the radial forearm flap and scapula flap, both of which can carry vascularized bone as well as skin and fascia. Not only have these contributions provided a greater variety of tissues for microvascular transfer, but they also have defined vascular pedicles that have a larger diameter and are, therefore, more reliable for anastomosis. The increased success rate, both technical and functional, that has been seen in this review reflects these advances and, it is hoped, will continue in parallel with future discovery.

The Role of Isolated Profundaplasty for the Treatment of Rest Pain

David M. McCoy, MD; Alan P. Sawchuk, MD; James J. Schuler, MD; Joseph R. Durham, MD; Jens Eldrup-Jorgensen, MD; Thomas H. Schwarcz, MD; Joseph P. Meyer, MD; D. Preston Flanigan, MD

• This study was undertaken to determine the efficacy and durability of profundaplasty and define preoperative factors predictive of success. The hospital charts, vascular laboratory data, and arteriograms of 20 patients having 21 isolated profundaplasties for ischemic rest pain between 1979 and 1987 were reviewed. Follow-up extended to 72 months (mean, 26 months). Early success was achieved in 12 extremities (57%) and life-table analysis showed continued success to six years in 11 extremities (55%). Of the multiple preoperative factors assessed, only a low-thigh/ankle gradient pressure index (TAGI) of less than 0.55 was predictive of success. Life-table analysis for limbs with a TAGI of less than 0.55 showed an 89% success rate at six years compared with only a 32% success rate for limbs with a TAGI of more than 0.55. Isolated profundaplasty for the treatment of ischemic rest pain can be an efficacious and durable procedure when patients are selected based on objective hemodynamic measurements.

(*Arch Surg* 1989;124:441-444)

The profunda femoris artery is the primary source of collateral flow to the lower extremity in the presence of superficial femoral and/or popliteal occlusion. Arterial reconstruction of the profunda femoris to relieve limb-threatening ischemia was first reported by Morris et al[1] in 1961. Profundaplasty is now usually employed in conjunction with aortofemoral or femoral-femoral bypass in patients with combined aortoiliac and superficial femoropopliteal occlusive disease. Profundaplasty is infrequently employed as an isolated procedure to relieve limb-threatening ischemia, and the limb salvage rate following isolated profundaplasty has varied from 23%[2] to 83%.[3] This article reports our experience with profundaplasty as a sole procedure for the relief of limb-threatening ischemic rest pain and assesses the accuracy of various preoperative hemodynamic measurements used as predictors of limb salvage.

PATIENTS, MATERIALS, AND METHODS

Between 1979 and 1987, 20 patients underwent 21 isolated profundaplasties for relief of ischemic rest pain on the vascular surgery services at the University of Illinois, Westside Veterans Administration, and Cook County hospitals, Chicago. Demographic and atherosclerotic risk factors are included in Tables 1 and 2. Patients were admitted to the hospital with a chief complaint of rest pain, and no patient had tissue loss when profundaplasty was performed. The duration of rest pain extended from two weeks to five months with a mean duration of 36 days. Fourteen patients had previously undergone 15 vascular reconstructive procedures related to the involved limb (Table 3).

Preoperative evaluation consisted of Doppler-derived blood pressures at the high-thigh, low-thigh, calf, and ankle levels. Three segmental pressure gradient indexes were then calculated from the Doppler-derived segmental pressures for each patient: (1) the low-thigh/ankle gradient pressure index (TAGI) calculated as the (low-thigh pressure–ankle pressure)/low-thigh pressure; (2) the profundapopliteal collateral index (PPCI) calculated as the (low-thigh pressure–calf pressure)/low-thigh pressure; and (3) the tibial gradient index (TG) calculated as the (calf pressure–ankle pressure)/calf pressure (Fig 1).

Fourteen of the 21 preoperative angiograms were obtained and evaluated using the recommendations of the Ad Hoc Committee on Reporting Standards of the Society for Vascular Surgery, to assess the quality of runoff arteries.[4] This system grades both the degree of stenosis and the relative contribution to outflow of each vessel, with the scale of disease ranging from 1 to 10 (with 1 signifying the least amount of disease and 10 signifying the greatest amount of disease). Oblique and lateral angiograms of the profunda femoris artery were not routinely performed preoperatively and, therefore, a calculation of the percent of stenosis of the profunda femoris artery could only be roughly estimated by evaluation of the anteroposterior roentgenograms.

A successful outcome was defined as the relief of rest pain and continued limb salvage for at least three months postoperatively. Patients who achieved a successful outcome (group A) were then compared with patients who did not achieve a successful outcome (group B).

The short- and long-term effects of isolated profundaplasty on rest pain and limb salvage were statistically analyzed by life-table and log-rank analyses (SAS).[5] Preoperative factors possibly predicting a successful outcome were analyzed using the Cox proportional hazards model of logistic regression (SAS). Results were interpreted as being statistically significant when $P<.05$.

RESULTS

There was no operative mortality, and the only complication consisted of one superficial wound infection. In the immediate postoperative period, 14 (67%) of 21 patients reported an improvement in rest pain, six patients (28%) reported no improvement in rest pain, and one patient (5%) reported a worsening of rest pain. There were 11 patients in group A (successful) and nine patients in group B (failure). One patient who reported immediate improvement in rest pain was subsequently unavailable for follow-up. Ten (91%) of 11 patients in group A reported immediate and continued improvement in rest pain, whereas three (33%) of nine patients in group B reported immediate improvement in rest pain that was not sustained at three months.

All nine patients in group B required at least one subsequent operative procedure. The procedures required consisted of one above-knee and five below-knee amputations, two femorotibial bypasses, and one femoropopliteal bypass. These procedures were performed between the first and 90th postoperative day with a mean of 26 days between the initial profundaplasty and the subsequent

procedure. The indications for additional procedures were continued or worsening rest pain in all nine patients, with four of the nine patients also exhibiting signs of early forefoot gangrene.

Follow-up extended to 72 months (mean, 26 months) and was 95% complete. The overall limb salvage rate for the 21 profundaplasties performed was 71%. Early success, as defined by relief of rest pain and continued limb salvage to at least three months postoperatively, was achieved in 12 extremities (57%). Life-table analysis showed continued success to six years in 11 extremities (55%) (Fig 2).

Possible preoperative predictors of success were evaluated and statistically analyzed using Cox proportional hazards multivariate logistic regression. The mean duration of rest pain (46 days, group A; 26 days, group B) and the presence or absence of diabetes or hypertension had no significant effect on the outcome ($P = .19$, .62, and .35, respectively). For all patients in the study, the mean preoperative low-thigh brachial index was 0.54, the mean calf brachial index was 0.26, the mean ankle brachial index was 0.21, and the mean foot brachial index was 0. Table 4 includes the mean preoperative pressure indexes at the low-thigh, calf, and ankle levels for groups A and B as well as the calculated P values for each anatomic level. None of the preoperative pressure indexes had a statistically significant effect on outcome of the procedure.

Evaluation of the preoperative angiograms revealed that eight patients had a runoff score of less than 5 at the popliteal level whereas six patients had a score of more than 5 at this level. Evaluation of the trifurcation and distal tibial vessels showed that all 14 patients had a score of more than 5 with a mean value of 8.5 signifying significant distal runoff disease. The mean runoff scores for preoperative angiograms at the popliteal and trifurcation and distal levels were 5.5 and 8.0 for group A and 6.8 and 9.2 for group B, respectively. Neither of these angiographic scores at these two levels had any effect on outcome ($P = .97$ and .26, respectively). The mean percent of stenosis at the origin of the profunda femoris artery was 53% for group A vs 50% for group B with no effect on outcome ($P = .72$).

Fig 1.—Determination of segmental pressure gradient indexes from preoperative segmental pressure measurements. CG indicates combined gradient index; PPCI, profundapopliteal collateral index; TG, tibial gradient index; AK, above-knee pressure; BK, below-knee pressure; HT, high thigh; and AP, ankle pressure. CG = thigh/ankle gradient pressure index (from Boren et al[7]).

Intraoperative records showed that the mean length of the profundaplasty performed was 5.6 cm, with 50% of the profunda arteries being endarterectomized. Saphenous vein, polytef (PTFE), endarterectomized superficial femoral artery, or Dacron was used to patch the profunda artery. Neither the length of the profundaplasty nor whether an endarterectomy was performed nor the type of patch material used had any bearing on outcome ($P = .49$, .43, and .45, respectively).

The mean PPCI for all patients was 0.43, and the mean TG for all patients was 0.17. The mean PPCI for group A was 0.28 compared with 0.64 for group B. This index had a P value tending toward significance when evaluated for its effect on outcome ($P = .10$). The mean TG was 0.14 for group A and 0.27 for group B. Multivariate logistic regression showed this index also tended toward predicting a significant effect on outcome ($P = .13$).

The mean TAGI for all patients was 0.53 (SD, 0.37). However, the mean TAGI in group A was 0.39 compared with 0.79 in group B. Multivariate logistic regression showed that the difference between those patients who had a successful outcome (group A) and those who failed (group B) had a calculated P value that was statistically significant ($P = .043$, likelihood ratio test for significance), implying that the lower the TAGI, the better the chances of achieving a successful outcome. Eight of 11 patients in group A had a TAGI of less than 0.55, whereas six of seven patients in

group B had a TAGI of more than 0.55. Life-table analysis for limbs with a TAGI of less than 0.55 showed an 89% success rate at six years compared with only a 32% success rate for limbs with a TAGI of more than 0.55 ($P = .01$ log-rank test) (Fig 3). Decision matrix analysis showed that a TAGI of less than 0.55 had a sensitivity of 89%, a specificity of 67%, an accuracy of 78%, a positive predictive value of 73%, and a negative predictive value of 86%.

COMMENT

Isolated profundaplasty is considered a relatively easy operation with minimal morbidity and mortality even when performed in high-risk patients who have undergone previous vascular procedures. This fact is borne out in our study in which 21 profundaplasties resulted in no mortality and a morbidity of 5%.

Hull et al,[6] Boren et al,[7] and Towne et al[8] stated that the possible benefit of profundaplasty may very well be to lower the amputation level from the above-knee to the below-knee level by increasing collateral flow through the profunda sytstem in patients in whom profundaplasty fails to achieve limb salvage. The overall mean increase in the calf brachial index in our study following profundaplasty was 0.23. Those patients in group B who subsequently required a below-knee amputation had a mean increase in the calf brachial index of 0.21, thus lending support to the concept that even if the limb cannot be salvaged, profundaplasty does substantially increase below-knee pressures probably enough to retain the knee and heal a below-knee amputation.

In our study, isolated profundaplasty for the relief of rest pain resulted in a success rate of 55% and a limb salvage rate of 71%. These rates agree with those in other reported series in the literature that indicate that the success rate of profundaplasty varies from 23% to 83% (Table 5).

Therefore, as can be seen from various series, isolated profundaplasty for rest pain/limb salvage has approximately a 50% chance of being successful. Because of this relatively low success rate, a variety of preoperative clinical, hemodynamic, and angiographic criteria have been evaluated in an attempt to predict which patients would achieve long-term limb salvage following isolated profundaplasty.[7,9-11]

The mean duration of rest pain was 20 days longer in group A than in group B. Although this preoperative variable did not have a statistically significant effect on outcome ($P = .18$), one may speculate that the longer the duration of symptoms preoperatively, the better the development of a collateral bed around the knee joint. Contrary to this, the small series of Rutledge and Burnham[9] (eight patients with rest pain) showed that the only patients who achieved a successful outcome from the procedure (two patients) were those who presented with the acute onset of rest pain.

Although the preoperative Doppler-derived segmental blood pressures had no statistically significant predictive value on the outcome of the procedure, it is interesting to compare the mean preoperative calf and ankle brachial indexes in groups A and B. The mean preoperative calf brachial index for group A was 0.13 higher than that for group B. This higher pressure at the calf level signifies

increased collateral circulation around the knee joint (geniculate and profundapopliteal collaterals) in the successful group. By performing a profundaplasty in the presence of increased collaterals, distal flow is increased. The mean preoperative ankle brachial index for group A was 0.16 higher than that for group B, signifying less resistance to flow from the low thigh to the ankle in group A patients.

The findings on the preoperative angiogram have been reported to be important as far as predicting outcome for isolated profundaplasty. Sladen and Burgess[10] identified four signs on the angiogram that were associated with failure: open profunda femoris inflow, competing superficial femoral flow, poor low-thigh collaterals, and poor calf artery visualization. Mitchell et al[11] found that arteriography provided the only reliable prognostic indicator and defined the following favorable signs: profunda orifice stenosis, minimal distal profunda occlusive disease, disease-free profunda collaterals, reconstitution of collaterals into a patent superficial femoral or popliteal artery, and good popliteal outflow. Taylor et al[12] noted that the complete absence of collateral vessels around the knee was associated with an unsuccessful result. Contrary to this, Ward and Morris-Jones[13] stated that the degree of preoperative profunda stenosis and distal runoff had no influence on the clinical outcome. Berguer et al,[14] analyzing the geometry of the profunda femoris artery, stated that in the presence of an occluded superficial femoral artery, even an apparently undiseased deep femoral artery represents an inflow stenosis of 50% and that even minimal disease in the deep femoral artery (0.5- to 1.0-mm thickening) considerably increases the percent of stenosis. Therefore, they concluded that the apparent absence of disease at the deep femoral artery on the preoperative angiogram is not a contraindication to performing a profundaplasty.

Unfortunately, we were unable to accurately measure percent of profunda stenosis on the preoperative angiogram. We do believe, however, that profundaplasty performed on a deep femoral artery with a higher percent of stenosis should result in a better outcome. Also, although this was not performed routinely in our patients intraoperatively, measurement of the pressure gradient between the area immediately proximal to the deep femoral artery stenosis and the area distal to this stenosis should reveal valuable information as to the applicability of performing a profundaplasty. The higher the pressure gradient, the better the results of the procedure should be. We believe a high pressure gradient along with adequate collateral outflow around the knee distally are prerequisites for the relief of rest pain and limb salvage following profundaplasty. The runoff status of the popliteal and trifurcation system of group B was worse than that of group A on the preoperative angiogram (6.8 and 9.2 vs 5.5 and 8.0, respectively) and although this difference was not statistically significant, one would expect that a less diseased popliteal and distal runoff system improves the chances that the procedure will work.

This study shows that those patients who reported an immediate improvement in rest pain postoperatively attained long-term success from the procedure (ten of 11 patients, 91% in group A), whereas in those patients who reported no improvement or worsening of their rest pain postoperatively (six of nine patients, 67%) in group B, the procedure was ultimately a failure. We have found no mention of this specific postoperative subjective indicator in the literature except by Martin and Jamieson,[15] who stated that it becomes necessary to rely on the patients' symptoms to ascertain the success of the operation and that this index is not very reliable.

The collateral gradient indexes calculated from the Doppler-derived segmental blood pressures were introduced by Boren et al.[7] They concluded that the most important predictor of success for their patients who had undergone profundaplasty was the PPCI ($P<.01$) and that in those patients with successfully revascularized limbs the mean PPCI was 0.18. A small PPCI means a well-vascularized profundapopliteal collateral system. They also concluded that the "combined gradient index," similar to the TAGI in our study, was predictive of success ($P<.01$). Ouriel et al[16] found that, of their patients who had undergone an inflow procedure with revascularization of the distal profunda femoris artery, eight of ten with a PPCI of more than 0.25 did not attain a successful result whereas 17 of 20 with a PPCI of less than 0.25 improved postoperatively. In our study, the TAGI proved to be the index most predictive of success and demonstrated an inverse correlation with success, ie, the lower the value of TAGI, the better the chance of relief of rest pain following isolated profundaplasty ($P=.04$). By calculating the TAGI, one is able to estimate the resistance of the tibial vessels. If the resistance between the vessels of the low thigh and the ankle is low, more nutrient blood will be carried to the foot and, therefore, increase the probability of alleviating rest pain. Those patients whose TAGI was less than 0.55 and who also experienced relief of their rest pain benefited from the procedure for up to six years.

Our results tend to agree with those of other series, ie, approximately 50% of patients who undergo an isolated profundaplasty for rest pain will be benefited by the procedure. Because of this less than acceptable success rate, the task facing vascular surgeons is to define those subsets of patients who will benefit most from isolated profundaplasty by careful evaluation of preoperative hemodynamic factors.

Recombinant Human Tumor Necrosis Factor Produces Hemodynamic Changes Characteristic of Sepsis and Endotoxemia

William J. Schirmer, MD; James M. Schirmer; Donald E. Fry, MD

• Tumor necrosis factor (TNF) is a macrophage-derived peptide mediator released during endotoxemia and sepsis. We examined the systemic and visceral hemodynamic response to low doses of human recombinant TNF in rats. Each animal received a 30-minute intravenous infusion of either saline solution (n = 8) or TNF (n = 8) in a dose of 0.25 mg/kg or 1.0 mg/kg. Thermodilution cardiac output, blood pressure, pulse, vascular resistance, effective hepatic blood flow (galactose clearance), and effective renal plasma flow (*p*-aminohippurate clearance) were determined at time = 2 hours. The 0.25-mg/kg dose had no apparent effect on systemic hemodynamics. The 1.0-mg/kg dose produced a hyperdynamic systemic circulatory response with an elevated cardiac output, tachycardia, and a diminished systemic vascular resistance. Effective hepatic blood flow was exquisitely sensitive to even the lowest dose of TNF, with a 29% reduction despite the normal cardiac output. Renal flow was unaffected by either dose. Tumor necrosis factor–induced systemic and visceral hemodynamic changes are remarkably similar to those seen in gram-negative sepsis, suggesting that TNF may occupy a proximal position in the pathogenesis of overwhelming infection.

(*Arch Surg* 1989;124:445-448)

Bacterial endotoxin administration produces a characteristic sequence of metabolic and hemodynamic alterations, culminating in widespread organ dysfunction, shock, and death. It is becoming increasingly evident that endotoxin itself does not directly damage host tissue; organ injury is the consequence of the ensuing activation of multiple humoral and cellular inflammatory mediators. Macrophages appear to occupy a pivotal position in this pathologic process. It has been shown that agents that stimulate reticuloendothelial hyperplasia render animals more susceptible to the lethal effects of endotoxin.[1] Furthermore, when harvested macrophages from endotoxin-sensitive mice are exposed to endotoxin, they produce a soluble factor that kills endotoxin-resistant mice.[2]

Tumor necrosis factor (TNF) is a macrophage-derived peptide mediator, the release of which is stimulated by endotoxin.[3] Animals given large doses of TNF develop hemodynamic collapse, hemoconcentration, metabolic acidosis, and widespread tissue damage.[4,5] Rats passively immunized against TNF are protected against endotoxin's lethal effects.[6] These observations suggest that TNF may be a primary mediator of shock and tissue injury during endotoxemia.

Whether TNF is a significant pathologic mediator during sepsis is not clear. In gram-negative sepsis, cardiac output is elevated and systemic vascular resistance is reduced, the reverse of what happens during endotoxemia. Lactic acidemia emerges prior to, rather than after, circulatory collapse.[7] Sepsis is further characterized by a redistribution of blood flow with reductions in hepatic and renal perfusion, which precede and appear to precipitate organ failure.[8,9] This study was undertaken to determine whether sublethal doses of TNF produce the earlier and more subtle perfusion abnormalities characteristic of hyperdynamic sepsis.

MATERIALS AND METHODS

Female Sprague-Dawley rats weighing 250 to 350 g were anesthetized with ketamine hydrochloride (5 mg/kg) and xylazine hydrochloride (37.5 mg/kg) by intraperitoneal injection. The right external jugular vein was cannulated with a 15-cm length of saline solution–filled polyethylene tubing passed centrally to the level of the right atrium. Each rat received a 1-mL/kg intravenous infusion of either saline (n = 8) or human recombinant TNF (H-rTNF) in doses of 0.25 μg/g (n = 8) or 1.0 μg/g (n = 8) over a 30-minute period. Hemodynamics were determined by methods outlined below at time = 2 hours after infusion.

Systemic Hemodynamics

A thermistor (YSI-511, Yellow Springs Instruments, Yellow Springs, Ohio) was inserted into each rat's aortic arch via the left

*Summary of changes in systemic hemodynamic variables at t = 2 hours induced by graded, sublethal doses of human recombinant tumor necrosis factor (TNF). While the lower TNF dose had no appreciable effect on systemic hemodynamics, the higher dose produced a hyperdynamic response characterized by an elevated cardiac output, tachycardia, and a diminished systemic vascular resistance. Values are given as mean ± SEM.

†$P<.01$ vs both other groups.

‡$P<.05$ vs both other groups.

common carotid artery shortly after the beginning of the intravenous infusion. Core body temperature was maintained within a range of 37°C ± 0.5°C by means of an infrared lamp. Thermodilution cardiac output (CO) was determined by the method of Isoyama et al[10] at time = 2 hours. A 0.15-mL bolus of room-temperature saline solution was rapidly injected via the central venous line, and the thermodilution curve was recorded from the thermistor tip to a dynagraph (Beckman R612, Beckman Instruments, Anaheim, Calif). Cardiac output was calculated as previously described by averaging duplicate curves and was expressed as milliliters per minute per 100 g of body weight.[10]

The aortic thermistor was removed and replaced with saline solution–filled polyethylene tubing. Mean arterial pressure (MAP) and heart rate (HR) were recorded via strain gauge to the dynagraph. Mean arterial pressure is expressed in millimeters of mercury and HR in beats per minute. Systemic vascular resistance was calculated by dividing MAP by CO, expressed in millimeters of mercury per milliliter per minute per 100 g of body weight. Hematocrit value was determined by centrifugation of a microcapillary tube of arterial blood. External body temperature was maintained within a range of 36°C ± 0.5°C.

Effective Hepatic and Renal Blood Flows

Effective hepatic blood flow (EHBF) was determined by the recently validated technique of galactose clearance at low concentrations.[8,11] Effective renal blood flow (ERBF) was determined by clearance of *p*-aminohippurate (PAH). Each rat received a priming intravenous dose of galactose (2.6 mg) and PAH (3.2 mg) combined in a 1.0-mL solution of saline at time = 90 minutes, followed immediately by a continuous intravenous infusion of galactose (13 mg/mL) and PAH (3.2 mg/mL) in saline solution via a Harvard pump at 0.04 mL/min.

Immediately following determination of systemic hemodynamics, five 100-μL arterial blood samples were collected into 1.1 mL of 62 mmol/L of sodium fluoride at five-minute intervals. The samples were centrifuged and the supernatant was frozen at −70°C until assay for galactose, which was performed by a manual adaptation of the automated fluorometric method of Henderson and Fales as described elsewhere.[8,12] Effective hepatic blood flow was calculated utilizing the Fick principle by the following equation: EHBF = I/css, where I indicates the infusion rate of galactose and css indicates the steady-state galactose concentration. Values are expressed in milliliters per minute per 100 g of body weight.

Four arterial blood samples were similarly collected at ten-minute intervals following a minimum of 60 minutes of equilibration for PAH assay. The 100-μL samples were immediately deproteinized in 200 μL of 5.1% perchloric acid. After centrifugation, the supernatants were frozen at −70°C until assay. The concentration of PAH was determined by spectrophotometric techniques described elsewhere.[13] Renal plasma flow was determined in a fashion analogous to that for EHBF, with the PAH infusion rate and concentration substituted for those of galactose in the preceding equation.

Statistics

Data are reported as the mean ± SEM. Between-group differences were determined by an analysis of variance followed by a Newman-Kuels multiple range test. Differences are reported as significant at either $P<.05$ or $P<.01$ confidence levels.

Fig 1.—Summary of percent change in systemic hemodynamic variables induced by graded, sublethal doses of tumor necrosis factor relative to sham control. Elevated cardiac output (CO) and pulse and diminished systemic vascular resistance (SVR) following higher tumor necrosis factor dose mimic hemodynamic pattern in gram-negative septicemia. Asterisks indicate $P<.01$ or $P<.05$ vs sham control (see Table for numerical data); MAP, mean arterial pressure; and HR, heart rate.

RESULTS

The systemic hemodynamic responses to the two doses of H-rTNF are compared with sham control values in the Table. The 0.25-mg/kg dose of H-rTNF had no appreciable effect on systemic hemodynamics. The 1.0-mg/kg dose caused a significant elevation in CO ($P<.01$) and HR ($P<.01$), and a reduction in systemic vascular resistance ($P<.05$). Mean arterial pressure remained relatively stable and the hematocrit value was unaffected, suggesting that fluid shifts were minor and, therefore, an unlikely influence on hemodynamics. Figure 1 graphically demonstrates how similarly the hemodynamic pattern induced by the higher H-rTNF dose mimics the hyperdynamic response typical of gram-negative sepsis, ie, tachycardia, elevated CO, and reduced peripheral vascular resistance.

The effects of the two H-rTNF doses on EHBF are graphically compared with a sham control value in Fig 2. Unlike systemic hemodynamics, EHBF appears to be exquisitely sensitive to even small doses of H-rTNF. The lowest dose of H-rTNF resulted in hepatic blood flow reduction ($P<.01$), despite the normal CO. In absolute terms, the higher dose affected EHBF to roughly the same degree as the lower dose, although relative to CO, EHBF seemed to be even further reduced. In contradistinction to liver flow, ERBF is unaffected by either dose of H-rTNF (Fig 3). Indeed, the trend suggested that H-rTNF may increase ERBF, although the differences did not achieve statistical significance.

Fig 2.—Effective hepatic blood flow (EHBF) plotted as function of tumor necrosis factor (TNF) dose. Effective hepatic blood flow appears to be exquisitely sensitive to TNF, as indicated by fall in EHBF following lower TNF dose despite fact that systemic hemodynamics were unaffected. Fall in EHBF following higher TNF dose is more dramatic given fact that cardiac output actually increased. Asterisks indicate $P<.01$ vs sham control.

Fig 3.—Effective renal blood flow (ERBF) plotted as function of tumor necrosis factor (TNF) dose. Unlike liver flow, ERPF remained unaffected by either dose of TNF.

COMMENT

Sepsis can be divided into various phases, beginning with the introduction of the offending organism into the circulatory system, followed by the initial activation of circulating inflammatory systems, and, finally, the full-blown activation of the host-defense response. Multiple organ injury does not become apparent until well after the full-blown response has been activated.[14] Macrophage-derived products may be particularly important mediators of the preorgan failure state. It is well documented that fever during gram-negative sepsis is mediated by interleukin 1, another macrophage-derived biologic response modifier.[15] Evidence is mounting that suggests that TNF is also a critical mediator of the septic response.

Tracey et al[4,5] reported that high TNF doses produce hemodynamic collapse, hemoconcentration, metabolic acidosis, and multiple organ injury in both rats and dogs. Typical histopathologic changes reported after TNF administration include extensive acute inflammation, capillary thrombosis, and focal necrosis in multiple vital organ beds.[4,5,16] It was suggested that the syndrome of lethal shock and multiple organ injury, which occurs during endotoxemia, could be elicited by TNF.[5] However, both the biochemical and histologic abnormalities were seen only with large TNF doses and only after profound alterations in systemic perfusion. It is quite plausible that the peripheral disturbances were simply the result of systemic circulatory collapse. Such a pattern is much different from that observed during true gram-negative sepsis, in which organ dysfunction and organ injury emerge in the face of an elevated, rather than a depressed, CO.

In our study, TNF given in sublethal doses produced the more-subtle hemodynamic alterations characteristic of sepsis. The 1.0-mg/kg TNF dose produced an elevated CO and a depressed systemic vascular resistance, and at the same time, reduced EHBF—a blood flow pattern remarkably similar to early sepsis.[8,9] Such a hyperdynamic state can also be produced by giving carefully titrated doses of endogenously administered endotoxin. Tumor necrosis factor is released during endotoxemia and bacteremia.[17,18] Our study suggests that TNF may occupy a proximal position in the pathogenesis of both sepsis and endotoxemia.

Hepatic blood flow appears to be exquisitely sensitive to TNF. In studies of septic rats, we found that EHBF fell despite a normal to elevated CO.[8,9,19] The role of impaired nutrient flow in the cause of organ dysfunction in sepsis has been previously established.[8,9,19-21] Mediators, including arachidonic acid metabolites, complement components, oxygen radicals, the coagulation system, neutrophils, and platelets, seem to be involved to one degree or another in these hepatic flow changes. The question naturally arises whether TNF contributes significantly to the pathologic changes during sepsis. Studies concerning the interruption of TNF synthesis or the inhibition of its action are required to clarify this issue.

The effects of TNF appear to be organ specific, ie, EHBF is reduced while ERBF remains unaffected. Other studies have shown that the lung appears to be another target organ for TNF-induced injury.[4,5] The liver and lung differ from the kidney in that they are reticuloendothelial organs that harbor large resident macrophage populations. Tumor necrosis factor may either act directly on or perhaps regulate the macrophage release of other pathogenic mediators, the effects of which are felt most keenly within the microenvironment in which they are released. It is of some interest that the acute hemodynamic effects of large doses of TNF are remarkably similar to those of another biological response modifier, interleukin 2. Interleukin 2 causes a vascular leak syndrome that primarily targets the lung, liver, spleen, and thymus.[22] Clarification of the causes of these organ-specific effects may help define the role of TNF in multiple organ systems failure.

In previous studies, we found that infusion of zymosan produced a hemodynamic profile similar to sepsis, ie, elevated CO and reduced hepatic flow, which correlated with the degree of complement activation.[23] However, in subsequent studies in which cobra venom factor was used to activate complement, hepatic blood flow was reduced but systemic hemodynamics remained unaffected.[24] In addition to activating complement, zymosan may stimulate TNF release by both complement-dependent and complement-independent activation of macrophages. Tumor necrosis factor stimulates neutrophil adherence to endothelial cells and enhances leukocyte-mediated killing of infectious organisms, well-organized properties of complement.[25,26] The true explanation for the hemodynamic changes following zymosan infusion (and perhaps for the changes during

sepsis) may involve an interplay between TNF, complement, and other circulating mediators.

Altered nutrient blood flow has been shown to precipitate organ dysfunction and failure in septic rats.[5,9,19-21] Whether TNF-induced hepatic ischemia is associated with hepatic dysfunction requires further study. Remick et al[16] reported that TNF given to mice produced profound disturbances in the endothelium of the gastrointestinal tract. The small-bowel villi were flattened and necrotic, and a study of the vasculature revealed neutrophil accumulation, endothelial cell blebs, gap formation, and exposed basement membrane. The measured reduction in EHBF in our study may reflect a primary disturbance of flow at the gut level rather than within the liver per se (EHBF equals nutrient hepatic arterial plus portal venous flow). A great deal of attention has recently been focused on bacterial translocation across the gut as a potential source of ongoing sepsis during multiple organ systems failure.[27,28] The results of our observations of possible gut flow disturbance and endothelial disruption suggest that TNF deserves to be considered a mediator of organ failure.

It is unlikely that the study of any single mediator will fully explain the complete spectrum of metabolic and hemodynamic abnormalities associated with sepsis. However, evidence is mounting to suggest a broad pathogenic role for TNF. Tumor necrosis factor is released after endotoxin challenge, and endotoxin's lethal effects can be attenuated by anti-TNF antibodies.[6,18] Tumor necrosis factor given to humans produces fever and stimulates release of stress hormones and acute-phase reactants.[29] Our study shows that low, sublethal doses of TNF produce systemic hemodynamic changes and early organ flow abnormalities characteristic of sepsis. A more complete understanding of the pathogenic significance of TNF awaits the development of specific inhibitors of its synthesis and actions.

This investigation was supported in part by US Veterans Administration.

The Association of *Escherichia coli* Virulence and Pulmonary Microvascular Damage

Roderick A. Barke, MD; David L. Dunn, MD, PhD; Agustin P. Dalmasso, MD;
Melody O'Connor-Allen, MD; Richard L. Simmons, MD; Edward W. Humphrey, MD, PhD

• Bacterial virulence indicates the degree of pathogenicity of a given strain of microbe for a given host. The effect of *Escherichia coli* virulence on lung microvascular permeability was studied in sheep with chronic pulmonary lymph fistulas following peritoneal contamination. The study was divided into four groups: (1) wild-type *E coli* (WT group, 2.5×10^9 colony-forming units [CFUs]/kg); (2) virulent *E coli* (PV group, 2.3×10^9 CFUs/kg); (3) nonvirulent *E coli* (PNV group, 2.6×10^9 CFUs/kg); (4) high-inoculum wild-type *E coli* (HIWT group, 6.1×10^9 CFUs/kg). In the late period (two to six hours), the increase in lung lymph flow in the PV group was significantly greater than the WT, PNV, and HIWT groups, with no difference noted among groups with respect to the pulmonary artery pressure, pulmonary wedge pressure, or albumin lymph/plasma ratio. It was concluded that (1) increased *E coli* virulence results in increased lung microvascular damage and (2) increased lung microvascular damage as a function of *E coli* virulence may not be solely due to increased bacterial numbers as a function of time.

(*Arch Surg* 1989;124:449-452)

Adult respiratory distress syndrome (ARDS) represents a final common pathway with multiple possible disease states as possible causal factors. One important causal factor is gram-negative bacterial sepsis. It is well known, however, that not all patients with gram-negative bacterial sepsis develop ARDS. Bacterial virulence is defined as the degree of pathogenicity of a given strain of microbe for a given host. Bacteria with various degrees of virulence may coexist in equilibrium with the host in a truce that is occasionally broken when factors that upset the delicate equilibrium come into play (immunosuppression, trauma, malnutrition, etc). We hypothesized that bacterial virulence factors may contribute to the incidence and severity of ARDS in gram-negative bacterial sepsis. To examine this question, we isolated three strains of *Escherichia coli* with different virulence as determined by 72-hour mortality in a rat peritonitis model. We then studied these three *E coli* strains in a sheep model and compared (1) damage to the pulmonary microvasculature, (2) hemodynamic failure, (3) neutropenia, and (4) classic and alternative pathway complement consumption.

MATERIALS AND METHODS

We prepared 23 yearling sheep (weight range, 35 to 55 kg) with chronic pulmonary lymph fistulas as described by Staub et al.[1] The experimental animal was allowed to recover from the operative procedures for at least two days. On the experimental day, the sheep was obtunded with pentobarbital sodium and placed on a volume-cycled ventilator with oxygen supplementation. The experimental animal was maintained in a paralyzed, obtunded state during the experimental period using pancuronium hydrochloride (0.1 mg/kg every four hours) and morphine sulfate (0.1 mg/kg every four hours). A Swan-Ganz catheter was passed into the pulmonary arterial circulation, and a polyethylene catheter was passed into the central aortic circulation. A central venous catheter was placed for intravenous fluid administration. Arterial blood gas and pH values were obtained with the ventilator, and oxygen supplementation was adjusted to obtain a baseline pH of 7.35 to 7.45, arterial oxygen pressure of 90 to 150 mm Hg, and arterial carbon dioxide pressure of 35 to 45 mm Hg. A 10 F pediatric feeding tube was placed in the right upper quadrant for injecting *E coli* into the peritoneal cavity. A right-upper-quadrant catheter placement was chosen based on previous experiments that indicated that this position yielded the most consistent response to *E coli* peritoneal contamination.[2]

Throughout every experiment, data were recorded with the sheep in the right lateral decubitus position. Pulmonary lymph volume was measured by accumulating lymph in heparinized, tared plastic vials during five- to ten-minute periods. The experimental groups were divided as follows: the passaged virulent *E coli* group (six sheep, PV group); the wild-type *E coli* group (six sheep, WT group); the passaged nonvirulent *E coli* group (six sheep, PNV group); and the high-inoculum wild-type *E coli* group (five sheep, HIWT group). The time during which data were collected was divided into a baseline period and an experimental period. The baseline period began after the experimental animal entered a steady state, as determined by constant pulmonary lymph flow and constant hemodynamic parameters. During this period, the following data were recorded: mean pulmonary artery pressure, mean pulmonary wedge pressure, mean aortic pressure, cardiac output, arterial blood gas and pH determinations, white blood cell count with the differential cell count, classic (CH_{50}) and alternative pathway (AH_{50}) hemolytic complement, lung lymph flow, and lung lymph and plasma for albumin concentration. These data were sampled at least four times throughout the one- to two-hour baseline interval.

After the baseline period, the experimental period was initiated by the injection of approximately 2.0×10^9 *E coli* per kilogram of body weight (PV, PNV, and WT groups) or 6.0×10^9 *E coli* per kilogram of body weight (HIWT group) into the peritoneal cavity through the previously placed right-upper-quadrant catheter. In addition to the continuous hemodynamic measurements, the data collected during the experimental period were as follows: cardiac output every 60 minutes; arterial blood gas and pH values every 30 minutes; pulmonary lymph flow every 30 minutes for two hours and then every hour; white blood cell count with the differential cell count; and CH_{50} and AH_{50} blood samples at 1, 3, 5, and 6 hours after peritoneal contamination. The duration of the experimental period was seven hours. Each animal in the PV, PNV, and WT groups was given 1 L of 0.9% normal saline solution during the six-hour experimental period. In the pilot studies, marked third-space losses in the HIWT group, in comparison with the other groups, resulted in a lower pulmonary wedge pressure and pulmonary artery pressure, resulting in the groups being noncomparable with respect to the hydrostatic component of pulmonary lymph flow. Accordingly, each animal in the HIWT group was given 0.9% normal saline solution at a rate such that the pulmonary wedge pressure as a function of time would match historical controls for the WT group.

Albumin concentrations were determined using the bromocresol green dye–binding method of Doumas and Biggs[3] and expressed in grams per deciliter. The arterial pH and arterial oxygen and carbon dioxide pressures were measured using a blood gas analyzer (Corning). The white blood cell count was performed using a hemacytometer (Neubauer). The blood cell differential count

Fig 1.—Effect of *Escherichia coli* virulence (passaged virulent, [PV], wild-type [WT], and passaged nonvirulent [PNV] groups) or increased inoculum (high-inoculum wild-type [HIWT] group) on pulmonary artery pressure, pulmonary wedge pressure, lung lymph flow, and albumin lymph/plasma ratio. Lung lymph flow (asterisks) in PV group greater than in either HIWT, WT or PNV groups ($P<.05$).

Fig 2.—Effect of *Escherichia coli* virulence (passaged virulent [PV], wild-type [WT], and passaged nonvirulent [PNV] groups) or increased inoculum (high-inoculum wild-type [HIWT] group) on cardiac output. Cardiac output (asterisks) in WT or PNV group greater than either PV or HIWT group ($P<.05$).

was performed on a blood smear using Wright's stain. The classic hemolytic complement pathway was measured by the method of Barta et al,[4] and the alternative complement pathway was measured according to the method of Platt-Mills and Ishizaka.[5]

A clinical isolate of *E coli*, obtained initially from a human peritoneal infection at the University of Minnesota Hospitals, Minneapolis, was used for the WT group. A more virulent form of this strain was obtained by injection of 2×10^8 colony-forming units (CFUs) intraperitoneally into rats with reisolation of the organisms after streak plating of swabs obtained from the peritoneal cavity of moribund animals after eight hours. This sequence was repeated eight times to obtain the isolate used in the PV group. A less virulent form of the WT group strain was obtained by streaking the initial isolate onto agar plates, followed by isolation of individual colonies. This sequence was repeated eight times. Each strain, thus prepared, was kept as frozen isolates and thawed out before each experiment. Each of the three isolates was grown overnight in brain-heart infusion broth and inoculated intraperitoneally into rats. The dose that produced 50% lethality was determined after 72 hours by the method of Reed and Muench[6] and was found to be as follows: PV group, 5.8×10^7 CFUs; WT group, 1.5×10^8 CFUs; and PNV group, 1.2×10^9 CFUs.

For each experimental animal, a loop sample from a stock plate culture from the appropriate experimental group was inoculated into brain-heart infusion broth and incubated in a shaker bath for 18 hours at 37°C. The *E coli* broth was then subjected to three cycles of centrifugation (1600 for ten minutes), with each cycle followed by resuspension in 0.9% normal saline solution. Initial approximation of bacterial numbers on the day of experimentation was made using a Klett-Summerson densitometer. Serial dilutions were then performed, agar pour plates were made, and exact enumeration was established by viable colony counting. Blood samples were obtained from each experimental group at 1, 3, 5, and 6 hours after inoculation and tested for the presence of *E coli*.

The initial number of *E coli* used in each experimental group was as follows: WT group, $2.5\pm0.4\times(10^9)$ CFUs/kg; PV group, $2.3\pm0.5\times(10^9)$ CFUs/kg; PNV group, $2.6\pm0.4\times(10^9)$ CFUs/kg; and HIWT group, $6.1\pm0.6\times(10^9)$ CFUs/kg. No significant difference among the initial number of bacteria among the WT, PV, or PNV groups was observed. The HIWT group inoculum was significantly greater ($P<.05$) than the other groups.

The mean and SE of the mean pulmonary artery pressure, mean pulmonary wedge pressure, albumin lymph/plasma ratio, lymph flow, and absolute neutrophil count were calculated as a function of time for each experimental group. The cardiac output was normalized per kilogram of body weight in each experiment, and

Fig 3.—Effect of *Escherichia coli* virulence (passaged virulent [PV], wild-type [WT], and passaged nonvirulent [PNV] groups) or increased inoculum (high-inoculum wild-type [HIWT] group) on absolute granulocyte count, CH_{50}, and AH_{50}. CH_{50} or AH_{50} (asterisks) in PV group less than either WT or PNV group ($P<.05$).

the mean and SE were calculated as a function of time for each experimental group. Since the baseline measurements of classic and alternative hemolytic complement varied significantly among the experimental groups, CH_{50} and AH_{50} were normalized in each experiment to the average baseline values and expressed as a percent of baseline. The PV group was then tested as a function of time against either the WT group, the PNV group, or the HIWT group using a *t* statistic for two means with significance accepted at the *P* less than .05 level. In addition, the PNV and HIWT groups were tested against the WT group as a function of time using a *t* statistic for two means. No animal in the HIWT group survived six hours, and since some animals in this group became moribund after four hours, no data were tested as a function of time beyond four hours in this group. The HIWT group survival distribution was compared with the PV group survival distribution using Gehan's generalized Wilcoxon test[7] with significance accepted at the *P* less than .05 level. Blood culture data were tested as a function of time using a Fisher's exact test with significance accepted at the *P* less than .05 level.

Fig 4.—Effect of *Escherichia coli* virulence (passaged virulent [PV], wild-type [WT], and passaged nonvirulent [PNV] groups) or increased inoculum (high-inoculum wild-type [HIWT] group) on incidence of positive blood cultures as function of time: one hour, HIWT greater than WT and PNV groups ($P<.01$); three hours, PV greater than WT and PNV groups ($P<.05$); three hours, HIWT greater than WT and PNV groups ($P<.01$); and six hours, PV greater than WT and PNV groups ($P<.05$).

RESULTS

During the following discussion, the time following the *E coli* peritoneal contamination has been divided into an early period (zero to two hours) and a late period (two to six hours).

During the early period (Fig 1), no significant difference in pulmonary hypertension, pulmonary wedge pressure, increased lung lymph flow, or the albumin lymph/plasma ratio was noted among the experimental groups. During the early period, no difference was noted among the groups with respect to cardiac output (Fig 2), granulocytopenia, and CH_{50} or AH_{50} (Fig 3). At one hour, the percent of positive blood cultures in the HIWT group was significantly greater than either the WT group or the PNV group.

During the late period (Fig 1), it is observed that no difference is noted among the WT, PNV, and HIWT groups with respect to pulmonary artery pressure, pulmonary wedge pressure and the albumin lymph/plasma ratio, noting that no data points are available after four hours in the HIWT group due to the animals' conditions. However, the lung lymph flow in the PV group was significantly greater ($P<.05$) than that of either the PNV, WT, or HIWT group. The cardiac output (Fig 2) in the WT and PNV groups was significantly greater ($P<.05$) than in either the PV or HIWT groups at four hours. In addition, the cardiac output in the WT and PNV groups was significantly greater ($P<.05$) than the PV group at five and six hours. During the late period (Fig 3), no significant difference is noted among the groups with respect to the absolute granulocyte count; however, the CH_{50} and AH_{50} in the PV group at five and six hours were significantly less ($P<.05$) than the CH_{50} and the AH_{50} in the PNV or WT groups.

The incidence of positive *E coli* blood cultures as a function of time in each experimental group is compared

in Fig 4. At one hour and three hours after peritoneal inoculation, the incidence of positive blood cultures in the HIWT group was greater than in either the WT or PNV groups ($P<.01$). At three and six hours after peritoneal inoculation, the incidence of positive blood cultures in the PV group was greater than in either the WT or PNV groups ($P<.05$).

The mortality in the HIWT group (100% mortality, six hours) was significantly greater than in the PV, WT, or PNV groups (0% mortality, six hours) ($P<.05$).

COMMENT

We have demonstrated that increased *E coli* virulence (PV group) resulted in increased lung microvascular injury when compared with the WT, PNV, or HIWT groups. The increase in microvascular injury in the PV group can be accounted for by two basic mechanisms. First, increased virulence may simply result in increased numbers of bacteria as a function of time. This is in agreement with the blood culture data that suggest increased numbers of blood-borne bacteria as a function of time in the PV group compared with either the WT or PNV groups. In this respect, increased pulmonary microvascular permeability as a function of increased virulence represents a variant of a dose-response curve.

A second possible mechanism for the observed increase in lung injury in the PV group is an intrinsic property of the PV group *E coli*, independent of increased bacterial numbers, that results in increased lung damage. This is suggested by the comparison of the PV group with the HIWT group. In the HIWT group, an initial inoculum was chosen that would result in an increased mortality compared with the PV group. Indeed, the mortality in the HIWT group was 100% six hours after inoculation. This increase in inoculum (HIWT group) and associated increased mortality did not result in comparable lung injury when compared with the PV group. Increased animal mortality as a function of increased inoculum is a well-described phenomenon and is usually attributed to increased bacterial numbers as a function of time following inoculation. This suggests that the increased lung microvascular injury observed in the PV group may have resulted not only secondary to increased bacterial numbers as a function of time but to an additional property intrinsic to the PV group *E coli*.

A possible explanation for the decreased lung injury in the HIWT group when compared with the PV group would be vascular derecruitment in the HIWT group secondary to cardiac failure, resulting in a decreased perfused membrane surface area. Although this may be contributory, the fact that the cardiac output in the HIWT group is not significantly different from the PV group at four hours after inoculation suggests that the perfused membrane areas are comparable.

Thus, while the increased lung injury observed in the PV group is certainly related to the increased bacterial numbers as a function of virulence, an intrinsic bacterial factor independent of bacterial numbers may be present. Such an intrinsic bacterial factor would have to modulate the mechanism(s) of lung injury in such a manner as to create a disproportional degree of lung injury compared with its effect on other organ systems, resulting in a mortality differential. If one assumes the macrophage to have a central role in the mechanism of injury following *E coli* sepsis and endotoxemia, then modulation of the response of the macrophage to endotoxin by a factor in the PV group *E coli* could explain such differences in injury as observed in this study. One recently implicated possible factor is cachetin. Produced by endotoxin-activated macrophages, cachetin has been thought to be an important mediator of the effect of endotoxin. It has been demonstrated that cachetin, when administered in a rat model, resulted in diffuse pulmonary inflammation and hemorrhage.[8] Thus, modulation of the macrophage or other host defenses by endotoxin or other virulence factors may result in differential end-organ injury.

Increased complement consumption in the PV group by both the classic and alternative pathways is demonstrated by significant decreases in CH_{50} and AH_{50} when compared with either the WT or PNV groups. This increased complement consumption is not associated with significant differences in the absolute granulocyte count between groups. The lack of correlation between the CH_{50} or AH_{50} and the degree of granulocytopenia in all experimental groups suggest leukotactic mediators other than those related to the complement cascade.

It can be hypothesized that the host-immune response and/or treatment-related factors (ie, antibiotic treatment) in the patient with gram-negative septicemia may be responsible for the selection of more virulent strains with resultant increased end-organ damage. In addition, bacteria with different properties may be selected out, such that end-organ damage may not simply be a function of bacterial numbers. Virulence-associated factors in gram-negative septicemia may result in a constellation of special properties that may be selected out in the course of patient management, placing the patient at increased risk for ARDS.

Bacterial surface structures are related to the properties of virulence. Although these antigens can be associated with the degree of tissue invasion, resistance to phagocytosis, and intestinal colonization, no single factor or antigen determines pathogenicity.[9] Phenotypes that are found more commonly in extraintestinal strains include hemolysin production, the biosynthesis of colicin V, and the hemagglutination of human erythrocytes (HA_h) in the presence of D-mannose.[10] Hemolysin has been demonstrated to be a cytotoxic factor,[11] colicin V is assumed to interfere with host-defense mechanisms, and HA_h is assumed to play a role in specific tissue adherence.[10] It is suggested that the investigation of bacterial phenotypes isolated from patients with gram-negative sepsis with and without associated ARDS may further elucidate the role of virulence in sepsis-related lung injury.

POWDER-FREE SURGICAL GLOVES CAN SAVE YOU MORE THAN TIME AND MONEY.

It's a fact. Using PRISTINE™ powder-free surgical gloves can save you time and money. No powders mean no valuable time spent performing a glove scrub, no basins, no wiping and no costly OR delays. And, because the highest quality, pure latex construction means maximum durability with fewer glove changes, you save money while gaining unequalled tactile sensitivity and excellent fit.

But, more than that, using PRISTINE powder-free gloves means the elimination of risks associated with all glove powders, and more protection for you and your patient.

HYPOALLERGENIC to protect your hands, PRISTINE gloves are 100% free of the powders, starches, talcs and silicas found on most other surgical gloves. And, by eliminating these powdered substances, PRISTINE gloves protect your hands from the chapping and cracking associated with powder-related dermatitis and hypersensitivity reactions.

Eliminate powder-related dermatitis and granulomatous reactions.

Even more important, no powder can mean no irritation or broken skin that could increase the potential for infection or the risk of other complications.

Surface of a PRISTINE powder-free surgical glove SEM (1000X) shows no foreign body or particulate contamination.

NO POWDER means fewer problems in the OR, too. No interior or exterior powders and no donning lubricants to leak from cuffs or escape during glove changes to contaminate equipment, test procedures or instruments.

For the patient, no powders in the OR mean none of the post-op complications such as granulomatous reactions, adhesions or peritonitis commonly linked to glove powders.

PRISTINE is the only glove with a patented friction-resistant interior surface for easy donning. Requires no donning lubricants and uses absolutely no powder.

To order, call (800) 545-5475, in CA (800) 547-3366. Complimentary samples may be requested by phone or by using the coupon below.

Effect of Eflorithine on Intestinal Regeneration

Jon S. Thompson, MD; Shailendra K. Saxena, MD, MS; John G. Sharp, PhD

• Patching intestinal defects with adjacent serosal surfaces results in the growth of new intestinal mucosa. Since polyamine biosynthesis is associated with cellular growth and differentiation, it may be important in this regenerative process. Our aim was to determine the effect of eflorithine (difluoromethylornithine), a specific inhibitor of polyamine synthesis, on intestinal regeneration. Forty-eight New Zealand white rabbits had 2 × 5-cm ileal defects patched with adjacent cecal serosal surface. One half of the animals took 2% eflorithine in drinking water postoperatively. Six animals in each group were killed 7, 14, 21, and 28 days after patching. There was no significant difference in neomucosal growth at any time. Villous height, disaccharidase activity, and crypt cell production were significantly lower in the eflorithine-treated animals. Eflorithine-treated animals had significantly lower ornithine decarboxylase activity and polyamine levels. Despite the inhibitory effect of eflorithine on polyamine synthesis and proliferative activity, epithelialization and contraction of the patched defect were not affected. These findings suggest that polyamine synthesis is important in proliferation and differentiation of cells in the neomucosa but does not influence cell migration in intestinal regeneration.

(*Arch Surg* 1989;124:454-457)

Patching intestinal defects with adjacent serosal surfaces results in the growth of new intestinal mucosa, termed *neomucosa*.[1] Growing neomucosa has been evaluated as a possible surgical therapy for patients with the short-bowel syndrome.[1-6] Neomucosal growth occurs by cell proliferation in the crypts in the surrounding normal mucosa and by migration of cells across the defect. The patched defect contracts to less than one half its initial size during the first week after patching. Presumably, intestinal transection is the initial stimulus for regeneration, but several factors affect the rate of this process, including size of the defect, luminal nutrition, intestinal location, and growth factors.[2-6]

The polyamines are intracellular cations that are important in cellular growth and differentiation.[7,8] Ornithine decarboxylase (ODC) is the rate-limiting enzyme of polyamine biosynthesis and therefore highly regulates the polyamine concentration. While increased polyamine synthesis occurs during mucosal cell proliferation, it is unclear whether it is essential to this process.[9] If ODC-mediated polyamine biosynthesis is important in intestinal regeneration, then stimuli that increase polyamine production might enhance this regenerative process.[5,10] The purpose of this study was to determine the effect of eflorithine (difluoromethylornithine), a specific inhibitor of ODC, on the growth of new intestinal mucosa after intestinal patching.

MATERIALS AND METHODS

Forty-eight male New Zealand white rabbits weighing 1.9 to 4.0 kg were included in the study. Two 2 × 5-cm ileal defects were patched with the adjacent colon serosal surface in each animal (Fig 1). One half of the animals took water and rabbit chow ad libitum. The other half took 2% eflorithine in drinking water and rabbit chow ad libitum. These animals drank an average of 190 mL of water per day, with an average dose of eflorithine of 1426 mg/kg/d. Six animals in each group were killed 7, 14, 21, and 28 days after operation. Neomucosal growth was determined by gross and microscopic measurements, including determinations of villous height. Tissue ODC activity, polyamine levels, and crypt cell production rate were measured to assess proliferative activity. Neomucosal function was evaluated by measuring in vitro glucose uptake and disaccharidase activity.

Operations were performed after an overnight fast using a sterile technique. Anesthesia was achieved with intramuscular ketamine hydrochloride and xylazine hydrochloride. Intestinal patching was performed by identifying the distal ileum and making two 5-cm incisions on the antimesenteric border, the first beginning 20 cm proximal to the ileocecal junction and the second beginning 10 cm proximal to the ileocecal junction. The defects were closed with a 2 × 5-cm patch of adjacent colon serosal surface with a continuous inverting 4-0 silk suture. The abdomen was irrigated with 10 mL of sterile water containing 100 mg of ampicillin sodium, and the incision was closed. The animals received 100 mg of ampicillin sodium intramuscularly preoperatively and twice daily for three days after operation. One hundred milliliters of 5% dextrose water was administered subcutaneously following the operation. The animals took nothing by mouth the first postoperative day, received fluids the second day, and took full alimentation after the third postoperative day.

After the animals were killed, the size of the patched defect and percentage of the defect covered with neomucosa were determined by measuring the transverse and longitudinal diameters and calculating the area of the ellipse ($\pi r_1 r_2$). Contraction was calculated by determining the patched area at death and expressing it as the percentage of the initial defect size (2 × 5 cm). Samples of

neomucosa were processed histologically and stained with hematoxylin-eosin. The measurement of villous height was made using an eyepiece micrometer.

Crypt cell production rate was determined by using a metaphase arrest technique.[5] Vincristine sulfate (1 mg) was administered by intraperitoneal injection two hours prior to killing. The mucosal sample was fixed in Carnoy's fixative and then hydrolyzed at 60°C for five minutes with Schiff's reagent. Crypts and villi were separated from the underlying connective tissue, and the crypts were dissected free using a dissecting microscope. Samples of crypts were transferred to a glass slide in 15% glacial acetic acid and were squashed for determination of the number of metaphases per crypt in a minimum of ten crypts. The mean of the metaphase counts of the crypts was taken as the reading for each sample. Crypt cell production rate was calculated assuming a linear accumulation for two hours.

Determination of net glucose uptake rates for both neomucosa and normal ileal mucosa was made using a double-isotope counting system with glucose labeled with carbon 14 and tritiated polyethylene glycol, where tritiated polyethylene glycol is the adherent fluid marker as described previously.[2] Three 5 × 5-mm disks of tissue were analyzed. The incubation medium included 10 mmol/L of glucose to which 15 µL of glucose labeled with carbon 14 (specific activity, 250 mCi/mmol/L) was added. Net uptake was expressed as nanomoles of glucose per minute per milligram of dry tissue weight. Disaccharidase activity in the neomucosa and normal mucosa was determined according to the method of Dahlquist.[11] Disaccharidase activity was expressed as micromoles of glucose per gram of protein per minute.

Polyamine levels were assayed in a mucosal homogenate containing 100 mg of mucosa in 50 mmol/L of potassium phosphate. The polyamines were separated by reverse-phase, ion-pair, high-performance liquid chromatography using a C18 column and quantitated by fluorescent detection after postcolumn derivatization with *o*-phthalaldehyde.[5] The mobile phases used in this separation consisted of two buffers: buffer A contained 85% 0.1 mol/L of acetic acid, 15% methyl alcohol, and 10 mmol/L of heptanesulfonic acid; buffer B contained 75% 0.25 mol/L of acetic acid and 25% methyl alcohol. The program was two minutes of 100% buffer B, which pumped for an additional 20 minutes. The height of the peak at the appropriate retention time was determined and concentrations were calculated based on a standard curve. Polyamine levels were expressed as picomoles per milligram of mucosa. Ornithine decarboxylase activity was determined by a radiometric technique in which the amount of ornithine labeled with carbon 14 was estimated.[6] Ornithine decarboxylase activity was expressed as picomoles of carbon dioxide per milligram of protein per 30 minutes.

Data are expressed as the means ± SEMs. The data were analyzed using one- and two-tailed Student's *t* tests, with $P<.05$ for significance levels.

RESULTS

Animals in both groups exhibited normal behavior. Control animals maintained body weight during the study. Animals receiving eflorithine lost 10% to 15% of body weight ($P<.05$) during the 14 days following operation, and body weight remained consistently below preoperative levels. Ten additional animals receiving eflorithine died during the first two weeks after operation and were noted to have markedly decreased oral intake. Bowel movements were of normal consistency in all animals. There were no complications related to the surgical procedure itself.

§Picomoles of carbon dioxide per milligram of protein per 30 minutes.

There was no significant difference in neomucosal growth between the two groups at any time (Table 1). The defects were almost completely covered by neomucosa three weeks after operation and had contracted to less than half their initial size. Grossly, there was no difference in neomucosal area. Microscopically, however, villous height was significantly less in the eflorithine-treated animals (Fig 2).

There were significant differences in neomucosal function three and four weeks after operation (Table 2). Sucrase and maltase activities were significantly less in the neomucosa of eflorithine-treated animals compared with the adjacent normal mucosa and the neomucosa in the control group. Disaccharidase activity in the normal mucosa of the eflorithine-treated group was significanly lower than that of the control group. However, glucose uptake, measured in vitro, was similar in both the neomucosa and normal mucosa of the two groups of animals.

Proliferative activity in the crypts of both neomucosa and normal mucosa decreased with eflorithine administration. Crypt cell production rate was significantly lower in the neomucosa of eflorithine-treated animals compared with control animals 2, 3, and 4 weeks after operation. Crypt cell production rate was suppressed to a greater

extent in the neomucosa than in adjacent normal mucosa in these animals.

Eflorithine-treated animals had lower ODC activity in both neomucosa and normal mucosa with significantly lower levels in neomucosa one week after operation and in adjacent normal mucosa three and four weeks postoperatively (Table 3). Putrescine and spermidine levels were also significantly lower in the eflorithine-treated animals, with the lowest levels attained in the second week after operation (Table 4).

COMMENT

Ornithine decarboxylase, the rate-limiting enzyme of polyamine biosynthesis that converts ornithine to putrescine, is irreversibly inhibited by the substrate analogue eflorithine.[7,8] Eflorithine, given enterally or parenterally, has been reported to cause a dose-dependent reduction in DNA and polyamine content of the intestinal mucosa. Villi become blunter and shorter and are lined by cuboidal to squamoid epithelium that frequently lacks a well-developed brush border.[12,13] The mucosal atrophy induced by eflorithine is transitory, indicating that intestinal cells are capable of compensating for the reduction in ODC-mediated polyamine synthesis.[12] Putrescine can be synthesized from spermidine, and this interconversion increases when the ODC pathway is inhibited.[14] Eflorithine abolishes the normal rise in ODC activity and mucosal polyamine content that accompanies intestinal adaptation resulting from intestinal resection and pancreaticobiliary diversion.[13,15,16] Eflorithine has also been shown to impair healing of gastric mucosal lesions caused by hypertonic saline, preventing the increased ODC activity that normally occurs during healing.[17] Thus, eflorithine might impair intestinal regeneration on patched intestinal defects.

In the present study, eflorithine suppressed polyamine synthesis and proliferative activity in neomucosa and normal adjacent intestinal mucosa beginning the second week after the patching procedure. Ornithine decarboxylase activity, mucosal polyamine content, and crypt cell production rate were all diminshed in the eflorithine-treated animals. The 60% decrease in ODC activity was somewhat less than the 85% to 95% decrease reported by others with a similar dose of eflorithine.[13,18] The intestinal polyamine content in the eflorithine-treated animals was normal seven days after patching but decreased thereafter. This may be secondary to impaired absorption of eflorithine

during the early postoperative period or the presence of stored polyamines that have not been depleted. Crypt cell production rate was highest 14 days after operation in the control animals, and eflorithine had a more pronounced inhibitory effect on the stimulated rather than basal proliferative activity.

The rate of epithelialization and extent of contraction of the patched defect were not affected by eflorithine administration. However, villi were shorter and brush border enzyme activity was less in the eflorithine-treated animals at each time point. These findings suggest that polyamine synthesis is important in proliferation and differentiation of cells in the neomucosa but is less important in cell migration and contraction during intestinal regeneration. Furthermore, proliferative activity in the intestinal crypts combined with cells made available by reducing villous size and cell populations is sufficient, even in the presence of eflorithine, to supply the epithelial cells necessary for continued cell migration onto the patched defect.

The findings of this study have implications for the mechanism of intestinal regeneration. This process involves migration of cells onto the patched defect, increased cellular proliferation in the crypts of the adjacent mucosa and then in the neomucosa, and contraction of the patched defect. The migrating cells proliferate and differentiate to form well-developed crypts and villi. Since epithelialization occurred at the normal rate in the eflorithine-treated animals, cell migration appears to be the rate-limiting factor rather than increased proliferative activity when sufficient cells are available for migration. This in turn implies that the ultimate determinant of intestinal epithelial regeneration is the perimeter of the normal epithelium surrounding any defect. However, we found previously that eflorithine partially inhibits urogastrone-stimulated epithelialization.[19] That observation suggests that increased cell proliferation is also an important factor in the rate of epithelialization. Contraction of the patched defect involves primarily subepithelial tissue responses, which is consistent with the failure of eflorithine to inhibit this process.[20]

This study was supported by grant DK36612 from the National Institutes of Health, Bethesda, Md.

The eflorithine was supplied by the Merrell Dow Research Institute, Cincinnati.

Effective Hepatic Blood Flow During Cardiopulmonary Bypass

William W. Hampton, MD; Michael C. Townsend, MD;
William J. Schirmer, MD; David M. Haybron, MD; Donald E. Fry, MD

• Hepatic dysfunction following cardiopulmonary bypass (CPB) is a relatively frequent finding, and jaundice occurring after CPB is associated with an increased mortality rate. Post-CPB jaundice may be a consequence of inadequate liver perfusion during CPB. To evaluate the potential impact of CPB on effective hepatic blood flow, 10 patients undergoing CPB for cardiac procedures were studied. Effective hepatic blood flow was measured in each patient during the operative procedure but before institution of CPB and during CPB as well. Effective hepatic blood flow was measured by the galactose clearance technique. Blood lactate and pyruvate levels were also measured before and during CPB. During CPB, effective hepatic blood flow was consistently reduced by an average of 19%. Although for most patients this reduction seems well tolerated, in a minority of patients it may contribute to postoperative hepatic dysfunction.

(*Arch Surg.* 1989;124:458-459)

Cardiac surgery necessitating cardiopulmonary bypass (CPB) has increased in scope and volume over the last 20 years. Although it has become an indispensable technique for most kinds of cardiac surgery, its use is not completely benign. Gastrointestinal complications of CPB contribute significant morbidity and mortality rates to the procedure,[1-3] and the incidence of post-CPB hyperbilirubinemia has been as high as 20% in large series.[1] Multiple studies have measured visceral blood flow during CPB in animals. Because of the different models used, there is really no consensus on the effects of CPB on visceral perfusion. Retrospective studies of patients undergoing CPB have implicated decreased organ perfusion during CPB or in the postoperative period, but difficulties in the measurement of hepatic blood flow have left this issue largely unexplored. In this study, we examined the effect of CPB on hepatic blood flow using the galactose clearance technique in patients undergoing cardiac procedures.

PATIENTS AND METHODS

Ten patients undergoing CPB were studied. Cardiopulmonary bypass was employed in each case using a roller pump (Pemco) with a disposable bubble oxygenator. Perfusion rates used in these 10 patients varied between 2.1 and 2.8 L/min per square meter. Hemodilution prime was used in all patients. In all but one patient, hypothermia of from 27°C to 29°C was employed. In one patient, normothermic CPB was used for the repair of an atrial septal defect. All patients in this study voluntarily signed an informed consent and the study was previously approved by the institutional review board at the Cleveland (Ohio) Veterans Administration Medical Center.

Twenty measurements of effective hepatic blood flow (EHBF) were made in 10 patients undergoing CPB for cardiac surgery. The first measurement was made after the patient was fully anesthetized and preparations were being made to begin CPB. The second measurement of EHBF was made for the patient after at least 30 minutes into the CPB procedure.

Accepted for publication November 14, 1988.

Measurement of EHBF was made by the method described by Henderson et al.[4] As soon as vascular access was obtained in each patient, blood samples were obtained for the analysis of baseline galactose levels. Patients were given an initial bolus of 12 mL of 5% D-galactose solution. This was followed by an infusion of D-galactose at 48 mL/h via a continuous infusion pump. While the patient was being draped, and more than 30 minutes after the bolus was administered, the first blood sample was obtained; thereafter, blood samples were obtained at 5- to 10-minute intervals for a total of five to nine blood samples for each patient. This group of blood samples was analyzed as described below to determine the pre-CPB EHBF. After each patient had been undergoing the CPB procedure for at least 30 minutes, a second set of six to nine blood samples was obtained at 5- to 10-minute intervals. This group of samples was analyzed for galactose concentration to determine the EHBF during CPB.

For each set of blood samples, the hematocrit was determined to allow for correction for hemodilution. Galactose concentration of each sample was determined by a manual modification of the automated fluorometric assay for galactose described by Henderson and Fales.[5] Plasma galactose concentration was then corrected to whole blood concentration by a factor of $1-(0.5\times\text{hematocrit})/100$. The steady-state concentraton of blood galactose was then determined from the average of each group of samples. The EHBF was calculated as follows: $\text{EHBF}=I/(C_{ss}-C_o)$, where I is the infusion rate of galactose; C_{ss}, mean steady-state blood galactose concentration; and C_o, baseline blood galactose concentration.

In addition, 8 of the 10 patients also had blood samples drawn near the middle of each EHBF measurement period for the determination of lactate and pyruvate levels. These blood samples were deproteinized immediately in perchloric acid and refrigerated until they could be assayed spectrophotometrically for blood lactate and pyruvate levels using specific kits (Sigma Chemical Co, St Louis, Mo).

RESULTS

In this group of patients, a consistent decrease in EHBF was demonstrated amounting to a 19% decrease during CPB. The data are summarized in Fig 1. All but one patient showed a decrease. On starting the CPB procedure, EHBF dropped from an average of 1468 ± 174 mL/min to 1190 ± 119 mL/min and the difference was statistically significant ($P<.05$; paired t test). During the period of CPB, the mean arterial pressure, hematocrit, and temperature were all reduced significantly, as seen below.

	Prior to CPB	During CPB
Mean arterial pressure, mm Hg	89.9 ± 2.9	72.7 ± 2.1
Hematocrit	0.334 ± 0.009	0.242 ± 0.011
Temperature, °C	35.6 ± 0.1	28.8 ± 0.9

During the period of operation before the CPB procedure began, the patients had a mean blood lactate level of 0.78 ± 0.13 mmol/L and mean pyruvate level of 0.112 ± 0.03 mmol/L. During CPB, mean blood lactate and pyruvate levels rose to 1.19 ± 0.18 and 0.142 ± 0.03 mmol/L as shown in Fig 2. While the increases in both lactate and pyruvate levels were statistically significant ($P<.05$), the lactate-pyruvate ratio remained constant.

COMMENT

The classic study of post-CPB jaundice by Sanderson et al[6] identified conditions related to development of this syndrome. They found that severity of cardiac disease,

Fig 1.—The effective hepatic blood flow (EHBF) of 10 patients before and during cardiopulmonary bypass (CPB).

Fig 2.—Blood lactate and pyruvate concentrations before and during cardiopulmonary bypass (CPB) in 10 patients.

erythrocyte breakdown, plasma hemoglobin, duration of CPB, and halothane anesthesia did not correlate with the development of post-CPB jaundice. In their analysis, patients undergoing multiple-valve replacements were most likely to have this syndrome develop. They proposed that hepatic congestion or some other condition may have predisposed some patients to the ill effects of inadequate perfusion, postoperative low-flow states, anoxia, or vasopressor drugs. Other retrospective studies have imputed a variety of possible risk factors for this syndrome[1,3] and the cause is still unknown. The study of Collins et al,[1] carried out more recently, demonstrated that post-CPB jaundice is as frequent or more frequent than in the early days of CPB. They reported an incidence of this syndrome of 20% and a mortality rate of 25% in those patients who had post-CPB jaundice.

Several studies of visceral perfusion have been performed in animals. However, the applicability of the various animal models used to the human situation makes interpretation difficult. Lees et al[7] studied visceral perfusion extensively during CPB in rhesus monkeys and concluded that hepatic blood flow was adequate. Unfortunately, CPB in their study was performed at flow rates adjusted to approximate the normal cardiac output of the awake animals, and hypothermia and hemodilution were not employed. Waldhausen et al[8] determined hepatic blood flow in dogs during CPB and found that at normal perfusion rates, total hepatic blood flow was normal but hepatic blood flow fell markedly as total body perfusion was reduced.

We are not aware of any previous efforts to measure hepatic perfusion in humans during CPB. Schenk et al[9] measured hepatic blood flow in patients under anesthesia during the course of end-to-side portacaval shunts using an electromagnetic flow meter. In that study, mean hepatic blood flow was 1004 ± 322 mL/min, which is lower than the measurements in this study, but it was in a group of patients with severe liver disease. The galactose clearance technique used in our experiments has been very useful in measuring hepatic perfusion in a variety of settings.[10,11] The technique is particularly applicable to the conditions of this study because it is a noninvasive technique that could be easily carried out without impinging on the patient's care during the operation. The disadvantage of the technique is that it is not capable of making instantaneous measurements of hepatic blood flow, as EHBF is calculated from the steady-state levels of blood galactose obtained after a period of equilibration.

The data indicate that EHBF was significantly decreased during CPB. Steadily increasing blood lactate levels indicate that decreased perfusion to other areas of the body may be of metabolic significance. Increased blood lactate levels during CPB have been previously documented.[12] However, our data indicate that the lactate-pyruvate ratio remained constant. Since the lactate-pyruvate ratio represents a systemic expression of the cytoplasmic redox state, the constancy of this molar relationship may reflect that all tissues are not adversely affected by CPB and that lactate may actually be serving as an energy substrate for other tissues. Additional studies will need to address whether the flow abnormalities of CPB are tissue specific or are a generalized phenomenon.

None of the patients examined in this study developed post-CPB jaundice. Further studies either of groups at high risk for developing post-CPB jaundice or of larger numbers of patients undergoing routine bypass are needed to determine whether alteration in EHBF is a significant variable in the development of post-CPB jaundice. If so, the methodology of galactose clearance may be a valuable technique in monitoring the effects of newer regimens to correct visceral perfusion abnormalities.

Concomitant Cholecystectomy for Asymptomatic Cholelithiasis

Larry E. Bragg, MD, Jon S. Thompson, MD

• The outcome of 68 patients with asymptomatic cholelithiasis undergoing laparotomy for other conditions was reviewed to determine those most likely to become symptomatic postoperatively. Thirty-seven patients (54%) became symptomatic postoperatively. Eight patients (22%) required cholecystectomy within 30 days of operation or within the same hospitalization. These patients fasted for a longer period of time postoperatively (15±21 vs 4±3 days) than those undergoing later cholecystectomy. Significantly more of these patients required transfusion (38% vs 7%), mechanical ventilation (50% vs 11%), and total parenteral nutrition (50% vs 18%). Cholelithiasis frequently becomes symptomatic after laparotomy for other intra-abdominal conditions. Patients who require mechanical ventilation, transfusions, and parenteral nutrition and who are slow to resume enteral nutrition are more likely to require early cholecystectomy. Concomitant cholecystectomy adds minimal morbidity to other procedures and should be undertaken unless specific contraindications exist, particularly in this high-risk group.

(*Arch Surg* 1989;124:460-462)

Asymptomatic cholelithiasis is detected in 20% to 30% of individuals at the time of operation for an unrelated intra-abdominal problem.[1,2] If left untreated, symptoms will develop in a large percentage of these patients in the postoperative period that necessitate subsequent cholecystectomy.[1,3] For this reason, concomitant cholecystectomy is frequently performed for asymptomatic biliary calculi at the time of laparotomy.

Although the safety of concomitant cholecystectomy has been demonstrated,[4-6] concerns about adding a second procedure frequently remain in patients who are often elderly and undergoing extensive procedures, have a limited life expectancy, or are in hemodynamically unstable condition. It would be beneficial to identify which patients are most likely to require subsequent cholecystectomy. To address this question, we reviewed the outcome of a group of patients with asymptomatic cholelithiasis who were undergoing laparotomy. The group was analyzed to evaluate the safety of concomitant cholecystectomy and the natural history of untreated cholelithiasis following operation, and to detect variables predicting the need for subsequent cholecystectomy.

PATIENTS AND METHODS

From January 1979 to December 1987, 156 patients with asymptomatic cholelithiasis underwent laparotomy for non–biliary tract disease. There were 90 men and 66 women, aged 20 to 87 years. Patients in whom asymptomatic cholelithiasis was detected preoperatively, intraoperatively, or postoperatively within six months of a previous laparotomy were included in this study. Individuals with biliary symptoms preoperatively or acalculous cholecystitis postoperatively were excluded. Charts were reviewed to determine the primary diagnosis and operation, the management of cholelithiasis, and postoperative morbidity and mortality. Patients not undergoing concomitant cholecystectomy were further evaluated to determine subsequent development of biliary symptoms and to identify factors contributing to the eventual need for cholecystectomy. Variables evaluated included the presence of cancer, diabetes mellitus, obesity, or multiple stones and prolonged fasting, total parenteral nutrition, transfusion, or mechanical ventilation following the original operative procedure. Statistical comparisons were made using the χ^2 test with $P<.05$ for significance levels.

RESULTS

The primary operations are shown in Table 1. The most frequently performed procedures in patients undergoing concomitant cholecystectomy were colectomy, gastric resection, and fundoplication. Procedures were similar in those patients not undergoing cholecystectomy. The diagnosis of cholelithiasis was established preoperatively in 75 patients (48%), intraoperatively in 57 patients (37%), and postoperatively in 24 patients (15%). Cholecystectomy was significantly more likely to be performed when cholelithiasis was diagnosed preoperatively ($P<.005$) (Table 2). Thirty-four patients underwent primary procedures that were performed emergently, and only ten (29%) of these patients had concomitant cholecystectomy. In contrast, concomitant cholecystectomy was performed in 79 (65%) of 122 patients undergoing elective procedures ($P<.005$).

Eighty-eight of the patients (65%) with cholelithiasis discovered preoperatively or intraoperatively underwent cholecystectomy at the time of the original operation. Twenty patients (23%) had intraoperative cholangiography and one (1%) required common bile duct exploration. There were 27 postoperative complications (31%), one of which was directly related to the cholecystectomy (subhepatic abscess), and there were six deaths (7%) in this group. The number of complications and deaths was not significantly different in the patients who did not have concomitant cholecystectomy (18% and 9%, respectively).

Sixty-eight patients did not undergo concomitant cholecystectomy. The most common reason for not performing cholecystectomy at the original operation when the presence of cholelithiasis was determined preoperatively or intraoperatively was unstable condition (n=16 [36%]), followed by a short life expectancy (n=10 [23%]), inadequate incision (n=9 [20%]), too much additional dissection (n=6 [14%]), and concern for increasing risk of infection (n=3 [7%]). Thirty-seven (54%) of these patients subsequently developed biliary symptoms and all but one required cholecystectomy. Twenty-six of the symptomatic patients (70%) required cholecystectomy within six months

of their original operation. Nine patients (28%) required common bile duct exploration. All patients 50 years of age or less (n=15) eventually required cholecystectomy. There were no other significant differences between patients who remained asymptomatic and those who required cholecystectomy (Table 3).

Eight (22%) of the 68 patients required a second operation for cholecystectomy within 30 days of the original operation or within the same hospitalization. Sixty-two percent of patients requiring early reoperation for cholecystectomy had undergone emergent primary procedures, whereas only 17% of individuals later requiring cholecystectomy had emergent primary operations ($P<.05$). Additionally, these patients who required early cholecystectomy fasted for a longer period of time following the original operation and were more likely to require transfusion, mechanical ventilation, and total parenteral nutrition than those undergoing cholecystectomy at a later date (Table 4). Four patients (50%) developed acute cholecystitis, six patients (75%) experienced complications during the hospitalization, and there were four deaths (50%) in this group of patients who developed early symptoms postoperatively. The two groups were similar with respect to age and the presence of cancer, diabetes mellitus, obesity, postoperative shock, multiple stones, and peritonitis.

COMMENT

The decision to combine cholecystectomy with other intra-abdominal procedures in individuals with biliary symptoms is clearly justified. The advantages of combining procedures include avoiding a second anesthetic and in many cases a second incision. The safety of concomitant cholecystectomy has been well documented. Schreiber et al[4] performed cholecystectomy on 39 patients during major abdominal operations with only one related complication. McSherry and Glenn[5] found little increase in the morbidity and mortality rates of patients undergoing cholecystectomy concomitant with another major intra-abdominal procedure. Kovalcik et al[6] likewise found that the rate of complications was only slightly increased when concomitant cholecystectomy was performed (14.3% vs 19.8%). Shennib et al[7] found no difference in outcome among patients undergoing elective colon resection and concomitant cholecystectomy, but they advised against combining cholecystectomy with emergent colon resections. In the present study, 88 patients underwent concomitant cholecystectomy with only one complication related to the biliary procedure.

The frequent utilization of abdominal ultrasonography

and computed tomography for the evaluation of intra-abdominal problems has resulted in the increasing identification of asymptomatic cholelithiasis. Studies of the natural history of asymptomatic gallstone disease have shown that biliary symptoms will develop in approximately 10% to 20% of these individuals.[8,9] We found previously that 70% of patients with asymptomatic gallstones developed symptoms within six months following laparotomy.[3] String[1] found that 65% of patients with asymptomatic gallstones developed symptoms following aortic reconstruction. In the present study, 37 (54%) of 68 patients with asymptomatic gallstones developed biliary symptoms following major abdominal operations.

Although many patients become symptomatic, it would be beneficial to avoid cholecystectomy in high-risk patients. Determination of factors predicting the development of symptomatic cholelithiasis would aid in the decision of whether to perform concomitant cholecystectomy. Identification of individuals most likely to become symptomatic would eliminate the need for cholecystectomy at a later date but would also avoid the potential complications of unnecessary cholecystectomy in individuals not at risk.

It is not known why the performance of a laparotomy alters the natural history of "silent" gallstones. Inflammation of the calculous gallbladder occurring postoperatively may be analogous to acute acalculous cholecystitis. The incidence of acalculous disease in patients in whom acute cholecystitis developed postoperatively has ranged from 35% to 62%.[10-12] The cause of inflammation remains unknown, but it is thought to be due to ischemia of the gallbladder wall or biliary stasis with distention of the gallbladder. Factors often present in the postoperative patient, and possibly predisposing to the development of acute cholecystitis, are hypotension, hypoxemia, fasting, dehydration, and blood transfusion.[10-15] The eight patients in this study who developed biliary symptoms during the original hospitalization displayed several of these characteristics that possibly placed them at risk for developing inflammation of the gallbladder. In comparison with the group in whom symptoms developed at a later date, significantly more patients with early symptoms fasted for a longer period of time and required total parenteral nutrition, mechanical ventilation, and transfusion.

Glenn[13] reported an association between prolonged fasting and acute cholecystitis. He proposed that in the absence of oral intake there is no stimulus for gallbladder contraction, and stagnation and inspissation of bile occur. This concept has been further supported by the demonstration of an increased frequency of cholelithiasis in patients receiving total parenteral nutrition and undergoing long periods of fasting.[16,17] Gafa et al[18] found that biliary tract sludge developed within nine days in five of 12 patients following gastrectomy and postoperative total parenteral nutrition. Positive pressure ventilation has been shown to result in bile stasis[19] and may also promote acute acalculous cholecystitis.[20] The increased bile pigment load resulting from blood transfusion was suggested as a mode of gallbladder injury by Lindberg et al.[21] The presence of calculi in the patients in whom early biliary symptoms developed in this study may also have contributed to the development of cholecystitis.

Operative procedures for symptomatic cholelithiasis occurring after laparotomy were frequently more extensive and associated with greater morbidity. Common bile duct exploration was required in nine patients (25%) undergoing cholecystectomy at a later date, whereas only one patient (1%) undergoing concomitant cholecystectomy required common duct exploration. Patients who required cholecystectomy during or within 30 days of the original hospitalization had significantly higher morbidity and mortality rates than patients undergoing concomitant cholecystectomy. Six (75%) of the eight patients requiring early reoperation experienced complications and four patients (50%) died. The increased morbidity and mortality rates in this group may have been related to the high incidence (50%) of acute cholecystitis in this group. The high complication rate associated with acute postoperative cholecystitis has been previously documented.[10-12]

Patients with asymptomatic cholelithiasis frequently develop biliary symptoms following an operation for unrelated intra-abdominal problems. Patients requiring mechanical ventilation, blood transfusions, and parenteral nutrition postoperatively and who are slow to resume enteral nutrition are more likely to require early cholecystectomy. Individuals who subsequently require cholecystectomy frequently undergo a more extensive biliary procedure. Since similar characteristics have been identified in patients in whom acalculous cholecystitis develops, the pathophysiologic mechanisms responsible for the development of cholecystitis in these patient populations may be similar. Concomitant cholecystectomy adds minimal morbidity to other procedures and should be undertaken unless specific contraindications exist, particularly in this high-risk group.

Reversal of Pigment Gallstone Disease in a Canine Model

Lillian G. Dawes, MD; David L. Nahrwold, MD; Sanford I. Roth, MD; Robert V. Rege, MD

• Unlike dietary-induced cholesterol gallstones, which may disappear spontaneously when the lithogenic diet is withdrawn, little is known about the natural history of pigment gallstones. We examined whether pigment gallstone disease, which can be uniformly induced in the dog by six weeks of a methionine-deficient diet, can be reversed by return to normal diet. As previously reported, all dogs develop pigment gallstones as well as significant increases in biliary total calcium, free ionized calcium, and cholesterol concentrations after six weeks of a lithogenic diet. These changes are accompanied by a significant increase in the concentration of unconjugated bile salts in bile. In addition, histologic changes in the gallbladder wall occur that are consistent with a moderate degree of chronic cholecystitis. This study clearly demonstrates that return to a normal diet for six weeks allows bile composition to normalize, gallstones to disappear in 50% of dogs, and gallbladder histologic changes to return toward normal. Thus, it would appear that pigment gallstone disease in this model may be reversible, at least early during its course. Although the relevance of these findings to pigment gallstones in humans must be established, the potential for nonoperative treatment of pigment gallstones should not be discounted.

(*Arch Surg* 1989;124:463-466)

Gallstone disease is a common medical problem: 500 000 cholecystectomies are performed annually in the United States alone. It thus accounts for significant morbidity and mortality and has a major impact on health care costs, exceeding $5 billion in medical expenses each year. Although once considered a surgical disease, simple, safe, and inexpensive alternatives to surgery are being investigated. Some success has been achieved with cholesterol gallstone dissolution,[1] but the number of actual candidates for dissolution therapy has been limited by the frequent presence of gallstones with high calcium contents or with "calcium shells" that cannot be consistently dissolved with present techniques and agents.[2]

Pigment gallstones, found in 10% to 30% of patients with gallstones,[3] are largely composed of calcium salts of bilirubin, carbonate, phosphate, and free fatty acids[4] and are therefore usually not amenable to dissolution therapy. Unfortunately, this type of stone is also often seen in those patients who would benefit most from a nonoperative alternative, that is, in high-surgical-risk patients such as the elderly and patients with liver disease. If pigment gallstone disease were potentially reversible, the development of dissolution agents for pigment and for other calcium-containing gallstones would greatly increase the applicability of dissolution therapy.

We herein examine whether pigment gallstone disease can be reversed in a dietary model. Dogs placed on a methionine-deficient, high-cholesterol diet (MDD) uniformly formed pigment stones that closely resembled human black pigment gallstones.[5,6] We have previously reported that 100% of dogs on this diet for six weeks develop alterations in bile composition and pigment gallstones.[7] In this study, we extend our previous work and examine the histologic changes that occur with stone formation. In addition, return to a regular diet reverses all alterations in bile composition, returns gallbladder histologic changes toward normal, and results in the disappearance of gallstones in 50% of dogs. Thus, pigment gallstone disease may be reversible, at least early during its course.

MATERIALS AND METHODS

Experimental Design

Bile samples from 12 mongrel dogs were collected at laparotomies performed before and during an MDD, which consistently produces gallstones.[5,6] The protocol for bile collection and the changes in bile composition that occurred after six weeks of MDD have previously been reported.[7] At the end of six weeks of MDD, each dog underwent laparotomy, aspiration of gallbladder bile, and palpation of the gallbladder for the presence of stones after it was emptied. Six dogs from our previous study were killed and their gallbladders were harvested for histologic examination. The remaining six dogs were allowed to recover from surgery, placed on a normal diet for an additional six-week period, and then killed. Bile was again collected for analysis, and the gallbladders were removed for microscopic evaluation. Comparisons were made for the presence and absence of stones, for gross and histologic evidence of cholecystitis, and for changes in bile composition among these dogs (MDD + N), dogs on a six-week lithogenic diet (MDD), and three dogs before MDD (normal).

Bile Analyses

Bile was immediately cultured for the presence of aerobic and anaerobic bacteria. The pH and carbon dioxide pressure (P_{CO_2}) were anaerobically determined in a blood gas analyzer (Instruments Laboratory model 1301). Total calcium concentration was measured by fluorometric titration (Calcette calcium analyzer model 4008) and free ionized calcium with a Ca^{++}-sensitive electrode (ICA calcium analyzer). The proportions of conjugated and unconjugated bile salts were determined by thin-layer chromatography separation.[8] Each fraction was eluted from the gel with methanol for quantitative analysis. Total, conjugated, and unconjugated bile salt concentrations were then determined by the 3 α-hydroxysteroid dehydrogenase method.[9] The biliary electrolytes sodium and potassium were measured by flame photometry. Biliary phospholipid and cholesterol concentrations were determined by end-point enzymatic analysis (Wako phospholipid assay kit and Boehring Mannheim Biochemical cholesterol assay kit).

Gallbladder Histology

Gallbladders were opened longitudinally, examined grossly for the presence of stones, and immediately fixed in 10% formaldehyde solution. Paraffin-embedded sections were stained with hematoxylin-eosin, and coded slides were evaluated by a pathologist, without knowledge of the treatment of the individual dogs. Six histologic values of cholecystitis were scored: (1) cellular inflammation, (2) dilatation of mucosal crypts, (3) villous atrophy, (4) thickness of mucosal surface mucin, (5) fibrosis of the gallbladder

Table 1.— Histologic Changes in Gallbladder During Stone Formation*

	No. of Dogs With Stones	Mean Histologic Score
Normal	0/12	1 ± 1
MDD	12/12	12 ± 1†
MDD + N	3/6	5 ± 2

*MDD indicates methionine-deficient diet; and MDD + N, MDD followed by a return to a normal diet.

†Significant difference from normal, $P<.05$.

Fig 1.—Normal canine gallbladder. There are prominent villi with narrow crypts. Subepithelial tissues are relatively free of inflammatory cells. Muscularis is unremarkable. Serosa contains fibrous and adipose tissue without inflammation (hematoxylin-eosin, original magnification ×49).

wall, and (6) deposition of submucosal pigment. Each value was scored on a scale of 0 (normal) to 4 (severe changes), with a maximum possible score of 24.

Statistical Analysis

Differences between groups were analyzed by analysis of variance. Differences in bile composition and gallbladder histology between normal and MDD dogs and normal and MDD + N dogs were also analyzed by Student's *t* test. The statistical data reported for the comparisons were calculated by unpaired analysis. Paired analysis was also done to compare the six MDD + N dogs with themselves before and after MDD. Statistical significances were similar by all methods used. Results are reported as the mean ± SEM.

RESULTS

All 12 dogs developed gallstones following six weeks of MDD (Table 1). Each dog had sludge and small stones in the aspirated bile, and, at laparotomy, larger stones were palpated in the gallbladder lumen. There was no perceivable difference between the six dogs that were killed immediately and the six dogs returned to a normal diet. Examination of the gallbladders harvested at six weeks of MDD contained multiple dark-brown to black, amorphous pigment gallstones ranging in size from 1 to 4 mm. The gallstones were accompanied in some cases by thick mucinous material and were embedded in biliary sludge. Bile cultures were sterile in all cases.

As would be expected, normal dogs showed no evidence of cholecystitis (Fig 1, Table 1), and the mean histologic score was correspondingly 1 ± 1. With stone formation, the gallbladder walls were thickened, and each gallbladder

Fig 2.—Full-thickness section of canine gallbladder after six weeks of lithogenic (methionine-deficient) diet. Villi are absent. Crypts are increased in thickness. There is marked increase in mucosal thickness with accompanying increase in lamina propria. Severe chronic inflammatory infiltrate is seen in lamina propria, and mild infiltrate is present in muscularis mucosa and submucosa. Muscularis is thickened. There is mild increase in fibrosis of serosa (hematoxylin-eosin, original magnification ×49).

Fig 3.—Higher-power section of gallbladder from dog on lithogenic diet demonstrating mucus retention and dilatation of crypts. There is moderate chronic inflammation of widened lamina propria (hematoxylin-eosin, original magnification ×196).

wall showed varying degrees of submucosal lymphocyte and plasma cell infiltration, atrophy of villi, dilatation of the mucosal crypts, fibrosis of the gallbladder wall, and deposition of pigment in macrophages below the mucosa. An abundant amount of mucin was adherent to the mucosa of many of the gallbladders (Figs 2 and 3). These changes represent a moderate degree of chronic cholecystitis as reflected in the mean histologic score of 12 ± 1.

Pigment gallstones were found in only three of six dogs that were returned to a normal diet for six weeks (Table 1), and their gallbladders appeared normal whether or not they contained gallstones. The stones that were present appeared more organized and were larger than those noted at six weeks of MDD, ranging from 2 to 8 mm. Moreover, there was marked improvement of the chronic cholecystitis (Fig 4, Table 1), reflected by a significant ($P<.05$) decrease in the mean histologic score to 5 ± 2. This score was not significantly different from the score for normal gallbladders. Dogs without stones had the most impressive recov-

Fig 4.—Full-thickness section of gallbladder in dogs with gallstones returned to regular diet for six weeks. Villi are present, though there is still some dilatation of crypt areas. Lamina propria is widened, and there is mild chronic inflammation of lamina propria. Submucosa, muscularis, and serosa are near normal (hematoxylin-eosin, original magnification ×49).

Table 2.—Acidification and Concentration of Gallbladder Biles*

Biliary Value	Normal	MDD	MDD+N
pH	6.14±0.05	6.29±0.10	6.25±0.07
P_{CO_2}, mm Hg	56.9±2.5	79.7±7.0	60.4±4.4
Sodium, mmol/L	252±3	237±5	249±3
Potassium, mmol/L	11.3±0.3	11.3±0.3	10.8±0.2
Bile salts, mmol/L	257±7	241±9	243±12
Phospholipids, mmol/L	34.7±1.3	37.8±2.2	37.3±1.8

*MDD indicates methionine-deficient diet; MDD+N, MDD followed by a return to a normal diet; and P_{CO_2}, carbon dioxide pressure. All values for the normal and MDD groups were previously reported. All values are mean±SEM.

ery, with the mean histologic score decreasing to 3±1, whereas dogs with stones improved yet had some evidence of chronic cholecystitis, with a mean score of 8±3. Therefore, a return to a normal diet for six weeks resulted in resolving cholecystitis in all and the disappearance of stones in 50% of the dogs.

The results of bile analysis in MDD+N dogs were compared with previously published[7] data in these dogs before and after six weeks of MDD. Note that pH, P_{CO_2}, Na^+, K^+, bile salts, and phospholipid concentration remained normal after the restoration of a regular diet (Table 2). This was also true for dogs that continued to have gallstones in their gallbladders. There was no significant change in the ability of any dogs to concentrate or acidify bile at any time during the study. In contrast, the previously noted 29% and 23% increases in biliary Ca and Ca^{++}, and a twofold increase in cholesterol concentration after six weeks of MDD, were completely reversed when dogs were put back on a diet of regular dog chow for six weeks (Table 3). The Ca, Ca^{++}, and cholesterol concentrations of 9.88±0.25, 3.14±0.14, and 0.7±0.06 mmol/L, respectively, in MDD+N dogs were thus essentially the same as the values of 10.16±0.19, 3.02±0.07, and 0.7±0.03 mmol/L, respectively, in normal dogs. Also, there was a significant increase in the concentration of unconjugated bile salts in bile after six weeks of MDD, increasing from 0.5±0.5 to 13±4 mmol/L ($P<.05$). This was completely reversed by return to a normal diet; no unconjugated bile salts were detected in any MDD+N dog (Table 3).

Table 3.—Reversal of Bile Composition*

	Calcium Ion	Calcium	Cholesterol	Unconjugated Bile Salts
Normal	3.02±.07	10.16±0.19	0.7±0.03	0.5±0.5
MDD	3.71±0.17†	13.11±0.57†	1.4±0.10†	12.6±4.1†
MDD+N	3.14±0.15	9.88±0.27	0.7±0.06	Undetectable

*MDD indicates methionine-deficient diet; and MDD+N, MDD followed by a return to a normal diet. All values are millimoles per liter, mean±SEM.
†Significant difference from normal, $P<.05$.

COMMENT

Until recently, the presence of gallstones alone was an indication for cholecystectomy, and operations were frequently performed in asymptomatic or mildly symptomatic patients. However, clearer understanding of the pathogenesis and natural history of gallstones has led to radical changes in our attitude and approach toward gallstone disease. Expectant therapy for silent gallstones is common and believed to be as safe as, or safer than, operative therapy,[10] and alternatives such as oral dissolution therapy,[1] percutaneous cholecystostomy with contact dissolution,[11] and gallstone lithotripsy[12] are now being performed in selected patients. Gallstone disease is now increasingly viewed as a potentially reversible process.

The possibility of cholesterol gallstone dissolution arose in part from observations in animal studies documenting that diet-induced gallstones disappear when animals are returned to a normal diet.[13-16] As early as 1956, Christensen et al[13] showed that cholesterol gallstones in hamsters would disappear when they were placed on a nonlithogenic diet. Chang et al[14] later showed that disappearance of cholesterol crystals and gallstones in prairie dogs is associated with a decrease in biliary cholesterol levels, suggesting that the decrease in biliary cholesterol saturation was directly related to resolubilization of cholesterol crystals and gallstones. To our knowledge, similar observations have not been previously made for pigment gallstones in either humans or animals.

The canine dietary model of pigment gallstones was chosen because pigment gallstones of substantial size are uniformly produced in six weeks along with abnormalities in bile composition. Yet, at this time, gallbladder function is still relatively normal.[7] Although we approached this study with the idea that pigment gallstone disease is irreversible, we found that bile composition normalized, chronic cholecystitis improved, and gallstones disappeared in half of the dogs six weeks after return to a normal diet. The findings of these studies are thus analogous to the animal studies of cholesterol gallstone disease discussed above.

The fate of the pigment gallstones that disappeared during this study is not known. Since pigment gallstones are highly insoluble, containing a high proportion of calcium salts and an insoluble residue thought to be a tightly cross-linked network polymer,[17,18] spontaneous dissolution is unlikely. However, either partial or total dissolution of stones should not be discounted. It is possible that pigment gallstones are initially not so insoluble, but that later changes such as cross-linking of the polymer might render them resistant to dissolution. If this is the case, they could have been dissolved or decreased in size.

If stones did not dissolve, they must have passed from the gallbladder through the cystic duct, entering the

duodenum via the common bile duct. Delius et al[19] recently implanted kidney stone fragments (insoluble in bile) ranging in size from 2 to 6 mm into normal canine gallbladders. At five weeks, the mean weight of stone fragments remaining in the gallbladders was one third of that implanted, and one third of dogs had gallbladders completely free of stone fragments. Thus, stones of size comparable with those seen in this study can spontaneously pass from the gallbladder into the duodenum in a relatively short time.

The fact that stones remained in some dogs after six weeks of normal diet may be a finding as important as stone disappearance. Despite normal bile composition and resolution of cholecystitis, gallstones were present in three of the dogs and these stones were more organized and slightly larger. Thus, although factors that resulted in pigment gallstones were present only transiently, gallstones persisted in several relatively normal gallbladders. One might speculate that pigment gallstones might form during transitory "lithogenic states" and perhaps, like cholesterol gallstones, could remain silent for long periods. In fact, at this early stage, these diet-induced gallstones may be analogous to biliary sludge. Similar to results seen herein, sludge in the gallbladder has been known to resolve or disappear when followed up by serial ultrasound examinations.[20,21] Although these speculations are intriguing, this short-term animal study was not designed to examine these issues.

Chronic cholecystitis has been noted histologically in this model at five and 12 months of the lithogenic diet,[6] yet this is the first report of cholecystitis as early as six weeks. The presence of these changes at this early stage suggests that they occur simultaneously with stone formation and are not secondary to the physical presence of gallstones. This is further supported by the partial resolution of cholecystitis in dogs that continued to harbor gallstones after six weeks of regular diet.

Histologic evidence of inflammation, cell proliferation, and mucin production has been previously reported before or early during stone formation in dietary models of gallstones.[22-25] Administration of the antibiotic lincomycin to guinea pigs causes early gallbladder inflammation and gallstone formation. In this model and in dihydrocholesterol-induced gallstones in rabbits, enhanced fluid transport across the gallbladder has been demonstrated even before the appearance of gallstones.[16] In addition, microscopic gallbladder changes have been found early during stone formation in rabbits fed dihydrocholesterol[16] and in mice fed a cholesterol–cholic acid diet.[25] As was seen in this model, cholecystitis improved in all these models when the lithogenic agent or diet was withdrawn.

Although the relevance of this animal study to humans must be established, these studies raise the possibility that pigment gallstone disease can be reversed at some point during its course. Thus, it is similar to early studies with cholesterol gallstones that, when combined with a thorough understanding of cholesterol solubility, led to successful cholesterol gallstone dissolution. However, it should be understood that it is not clear from this study whether the stones dissolved or passed from the gallbladder via the cystic duct. In either case, the potential for nonoperative treatment of pigment gallstones should not be discounted.

Although an acceptable agent for pigment gallstone dissolution has not yet been found, there are a few reports of successful dissolution of stones containing calcium salts. Calcium carbonate pancreatic stones in the dog have been experimentally dissolved with trimethadione,[26] and there has been some success with in vitro dissolution of calcium bilirubinate stones with sodium–edetic acid solutions.[27] Further investigation into dissolution agents for calcium salts along with a better understanding of the pathogenesis of pigment gallstones may lead to nonoperative alternatives for pigment gallstone disease. Moreover, if the gallstones disappeared after reversal of abnormalities in gallbladder bile composition by passage into the duodenum, rather than by dissolution, it might be possible to treat this type of gallstone by fragmentation (gallstone lithotripsy).

This work was supported by Merit Review grant from the Veterans Administration.

Terminal Loop Cutaneous Ureterostomy in Cadaveric Kidney Transplantation

R. Neal Garrison, MD; Frederick R. Bentley, MD; Mohammad Amin, MD

• The presence of a nonfunctional bladder is a common finding in some patients with end-stage renal disease in whom transplantation is a proposed option. Over the last 20 years, we have performed six terminal loop cutaneous ureterostomies for urinary drainage during kidney transplantation. Neurogenic bladder in five patients and exstrophy in one patient prohibited use of the bladder. Four long-term graft survivors (19 months and 4, 10, and 20 years) experienced no short-term problems with the procedure, but two episodes of pyelonephritis have occurred. In our patients no graft dysfunction or loss could be attributed to infection, and no stomal stenosis or revision has occurred. We conclude that terminal loop cutaneous ureterostomy is feasible using normal-caliber ureters, and is a safe, effective means of urinary drainage during kidney transplantation when the bladder is not available. It also eliminates the necessity of preparatory bowel surgery that has its attendant risk of contamination in an immunocompromised patient.

(*Arch Surg* 1989;124:467-469)

A greater number of patients with nonfunctional lower urinary tracts are currently being considered as candidates for renal transplantation as immunosuppression has improved. Various methods of urinary drainage have been recommended as alternatives to the standard ureterovesical anastomosis when rehabilitation of the bladder is not possible. Using either long-term intermittent self-catheterization following a ureterovesical anastomosis or a cutaneous ileal conduit with a ureterointestinal connection are the techniques used most frequently.[1,2] Infection involving the upper urinary tract that leads to graft loss, and occasionally death, is a problem when utilizing these techniques, because differentiation between urosepsis and rejection can be difficult in a patient with chronic bacteriuria. In addition, preparatory intestinal surgery is needed several weeks prior to the transplantation when the ileal conduit technique is chosen, placing the patient at further risk for septic complications to occur.

Cutaneous ureterostomy was frequently used in the thigh or other sites when kidneys were initially transplanted.[3] Transplantation into the iliac fossa with end-ureterocutaneostomy was described by Kuss and associates[4] in 1951, although the results were disappointing due to the necrosis of the ureter in most of the cases. Martin and associates[5] utilized this technique in four patients, but the long-term function was apparently not good, since they saw no future for the technique. Amin and associates[6] reported on three patients in whom a new technique of terminal loop cutaneous ureterostomy was employed with good initial and long-term results. This report is a follow-up of these initial patients and three other patients. The first and second of these initial patients continue to have normal kidney function 20 and ten years, respectively, after kidney transplantation.

PATIENTS AND METHODS

Patients

A review of the records of all patients who had received a kidney transplant from the University of Louisville Transplant Program at Jewish Hospital yielded six patients in whom a terminal loop cutaneous ureterostomy was the method used for urinary drainage. The individual patient records were reviewed and the patient group demographics listed. The indicating symptom that resulted in kidney transplantation was noted, along with the reason cutaneous drainage was utilized. The anatomic specifics of the donor organ and the type of immunosuppression used were noted, along with the morbidity and mortality for the transplantation. The long-term complications and the current status of the patient and graft were listed. Specific attention was given to the occurrence of upper urinary tract infection and complications directly related to the cutaneous drainage.

Technique

A standard oblique curvilinear kidney transplant incision in the lower quadrant of the abdomen is utilized, and the vascular anastomosis is completed with the available recipient vessels, as dictated by the donor vessel anatomy. An adequate length of donor ureter is necessary to reach the prechosen stomal site in a gentle sweep, and to fashion the terminal loop once the kidney is placed in the retroperitoneal iliac fossa. A length of ureter that reaches comfortably to the bladder is ample to avoid tension on the ureter at the stomal site. The site of the stoma is determined by previous scars and the topography of the abdominal wall, but is usually selected below the level of the umbilicus, and medial to the rectus sheath border. The distal end of the ureter is ligated securely with an absorbable ligature, and a small oval disk of skin, fascia, and muscle is excised at the stomal site so that the ureter can be brought out in a tension-free fashion. The ureter exits the skin in the form of a loop, leaving the terminal ligated segment buried in the abdominal wall, as pictured in the Figure. The fascia beneath the loop is closed for a short distance with absorbable suture so that retraction of the exposed ureter is prevented. The exterior loop of ureter is then incised in a longitudinal fashion, and the edges are sutured to the skin with 4-0 absorbable suture material.

A small 5-F pediatric feeding tube is used as a ureteral stent for several postoperative days to monitor function and bypass any obstruction that may result from early stomal edema. A temporary adhesive ostomy bag is fitted to the skin edges around the stomal site and stent, to be replaced with a permanent fitted ureterostomy appliance when healing has occurred. Prior to removal of the stent, a retrograde contrast study is performed to assure patency. The resultant stoma appears as a double-barrel ureterostomy with only the proximal end functional.

RESULTS

Over a 20-year period, six patients have undergone a terminal loop cutaneous ureterostomy at the time of kidney transplantation. The individual case outlines are listed in the Table. There were four male and two female patients, with an age range of 8 to 50 years. Five patients had a neurogenic bladder secondary to a variety of causes as the indication for utilizing cutaneous drainage, while one patient had exstrophy of the bladder as an indicator. All six patients had end-stage renal disease, which was secondary to chronic suppurative pyelonephritis, and had

Technique of terminal loop cutaneous ureterostomy.

Case Outlines of Six Renal Transplant Recipients Who Underwent Cutaneous Ureterostomy

Patient Age, y/Sex	Primary Urologic Abnormality	Graft Outcome	Patient Outcome
8/F	Neurogenic bladder	Functioning at 20 y	Alive
25/F	Meningomyelocele with neurogenic bladder	Functioning at 10 y	Alive
20/M	Paraplegia with neurogenic bladder	Functioning at death	Death at 52 d
29/M	Neurogenic bladder	Chronic rejection at 19 mo	Alive
50/F	Paraplegia with neurogenic bladder	Acute tubular necrosis at death	Death at 38 d
33/M	Exstrophy of bladder	Functioning at 4 y	Alive

undergone bilateral nephrectomy for infection control. Immunosuppression therapy consisted of azathioprine and prednisone, with cyclosporine added to form a triple-drug regimen in the patient with exstrophy.

Terminal loop cutaneous drainage was used as the planned primary procedure in all six cases. All grafts were from adult cadaver donors (five locally procured and one imported), had a single artery and vein as vascular conduits, and had more than an adequate length of single ureter to reach the skin surface. Three grafts had immediate function, while three experienced acute tubular necrosis and delayed function. No short-term complications could be attributed to the use of a cutaneous ureterostomy.

All short-term complications occurred in two patients and resulted in both patients dying. In one patient, a short-term rejection episode occurred in a zero-antigen matched graft ten days following transplantation. Treatment of this rejection allowed the return of renal function, but a subsequent gastrointestinal bleed required operative intervention for control. An invasive *Candida albicans* infection developed and led to the patient's death 52 days after the transplantation. The second death occurred in a similar manner, with treatment of a rejection episode leading to duodenal ulceration and perforation. A polymicrobial invasive peritonitis led to multiple organ system failure and death 38 days after the transplant procedure.

One patient experienced long-term rejection, and the patient resumed dialysis 19 months after the transplantation. Three functioning grafts were present 20, 10, and 4 years following the procedure. Two episodes of acute polynephritis have occurred in these functional grafts. One was associated with encrustations at the stomal site, which required simple débridement without revision of the stoma. The second incidence of invasive upper tract infection occurred in association with lymphocele obstruction of the ureter and was relieved with operative drainage of the lymphocele. No graft dysfunction or death has occurred secondary to pyelonephritis.

COMMENT

Most lower urinary tract problems that are encountered in potential renal transplant patients can be corrected, and the bladder can be made suitable for urinary drainage. However, a small group of transplant recipients may have an irreversibly damaged and nonfunctional bladder, and require an alternative method of drainage other than a ureterovesical connection. The patients in this latter group almost always have a congenital or acquired abnormality that abolishes adequate lower urinary tract function. The eligibility of these patients for renal transplantation is currently limited only by the enthusiasm of the transplant team. Once native kidney infection is controlled, there is usually no medical contraindication to kidney transplantation in this group of generally young and healthy patients.

Since the intestinal conduit was utilized by Kelley and associates[7] in 1966 for urinary drainage in renal transplantation, this procedure has been recommended by most authors. However, there is an apparent high complication rate and a significant mortality associated with this procedure. Stenzel and associates[1] reported that three of eight patients had ureteral stenosis requiring another operation. Glass and associates,[8] in a report of five patients and a review of the literature on renal transplantation using intestinal conduits, found that 22 (32%) of 68 patients suffered a total of 29 complications attributed to the conduit. Eighteen septic complications directly resulted in nine deaths in these 68 patients, and the sepsis was usually associated with strictures or ileal calculi. Patients with ileal conduits tend to form stones, and the resultant foreign-body obstruction affords bacterial loop colonization the opportunity for invasive infection of the upper urinary tract. In these patients, the differentiation between pyelonephritis and rejection can lead to critical delays and, at times, an inappropriate elevation in immunosuppressive therapy. Although half of the patients described by Glass et al received organs from living donors, the functional graft survival rate was only 52%.

The intestinal conduit method requires either a preparatory procedure several weeks prior to transplantation or an enterotomy at the time of engrafting. The former is preferred to avoid contamination by bowel soilage in an immunosuppressed patient. Even when constructed in advance, this method has technical factors that frequently lead to complications. Glass et al[8] reported that six complications were associated just with the creation of the stoma or the restoration of intestinal continuity. Ureteral stenosis with some degree of upper urinary tract obstruction and dilation and frequent ureteral reflux are recalcitrant problems, while the risk of peritoneal soilage has led to the recommendation that the anastomoses between the ureter and bowel segment be done and left in the extraperitoneal space if technically feasible.

An attractive alternative to intestinal diversion in some patients who simply have a neurogenic bladder is the

procedure of chronic intermittent catheterization. Since its introduction by Guttman and Frankel[9] for the management of patients following spinal cord trauma, this technique has been used with varying success in the management of patients with a neurogenic bladder requiring kidney transplantation. However, the introduction of bacteria into the bladder of a transplant recipient is of concern for transplant surgeons, especially in their patients who have neurogenic bladder dysfunction where reflux occurs frequently. In a group of patients managed with clean intermittent catheterization followed up for a variable period, Barnett and associates[10] reported that about half had experienced bacteriuria or clinical urinary tract infections. This incidence compared favorably to the almost 100% incidence of bacteriuria in patients with intestinal conduits. Overall graft loss, renal dysfunction, or urosepsis could not be attributed to the intermittent catheter technique of bladder drainage. Despite the fact that some of these patients had only asymptomatic bacteriuria, Barnett and associates were concerned that a fatal infection could occur and cautioned that careful patient selection and instruction was necessary for this method to be useful.

Intermittent catheterization could have been utilized in several of our patients who were operated on earlier. In fact, in two recent transplant recipients, one, a diabetic patient with a neurogenic bladder who underwent a renal graft, and the other, a similar diabetic patient who received a combined renal and pancreas allograft with bladder drainage, the intermittent clean catheter technique has been used successfully by our service. Neither intermittent catheterization nor cutaneous drainage should be utilized to the exclusion of the other. Patient concerns, convenience, the medical status, and the social care aspects of each recipient must be considered when choosing the procedure for urinary drainage.

We currently consider those patients with neurogenic bladder who have a demonstrated inability or aversion to learn the intermittent self-catheter technique to be candidates for cutaneous ureterostomy drainage. Similarly, a patient with a disability that prevents him or her from undergoing the intermittent catheter procedure in a clean and safe manner is considered a candidate for cutaneous ureterostomy. Clearly, when the bladder is not available due to a congenital or traumatic abnormality, cutaneous drainage is the only option that will allow a successful transplant.

From previously described experiences, it would appear that no single method for urinary drainage of a transplanted kidney has proved ideal when a dysfunctional bladder is present. A successful cutaneous ureterostomy, where there is simplicity, an immediate availability for function, a low incidence of reflux, and no need to involve the intestinal tract, would have many advantages. Stomal complications and urosepsis are thought to be the major drawbacks of using a terminal cutaneous ureterostomy in a transplant recipient. A normal-caliber ureter removed from the donor has a tenuous blood supply, and this fact alone is thought to be the primary reason for stomal stenosis. However, Amin and associates,[11] in an experimental study in dogs and in a clinical series, reported that neovascularization of an isolated ureter occurred from the surrounding tissue when a terminal loop was used to construct the cutaneous ureterostomy. In this study, only one of 20 patients who required urinary diversion for a variety of reasons suffered a stomal stenosis requiring intubation.

Terminal loop cutaneous ureterostomy as described by Amin et al[11] and outlined herein has been used by our service for over 20 years with good results in both transplant recipients and in other patients requiring urinary drainage by the cutaneous route. In the present report, this technique has been utilized in six cadaveric kidney transplant recipients with moderate success. Four long-term graft survivors experienced no short- or long-term complications with the surgical procedure. There has been no stomal stenosis, and no stomal revisions have been needed. Encrustations requiring simple débridement occurred in the longest functional graft recipient, and only one invasive infection associated with ureteral obstruction from a lymphocele that required internal drainage has been documented. Similarly, the two early graft losses were not related to the type of urinary drainage used.

All patients continue to receive long-term urinary antisepsis medication since they do have constant bacteriuria, and the risk of urosepsis is always present and real. In these patients, the differential evaluation between urosepsis and rejection would appear to be simplified. Retrograde urography of the transplanted kidney is an easy procedure in those cases of renal dysfunction and, in our experience, invasive infection only occurs in the setting of urinary obstruction. The ureterostomy stoma does appear to reflect various changes within the graft after an initial period of edema and can be used as an indication of rejection. In two of our cases, marked edema of the stoma coincided with acute allograft rejection, and in one case, a small biopsy of the stoma showed lymphocytic infiltration at the time of the rejection episode. Stoma edema reversed in both instances with treatment and control of the rejection.

Terminal loop cutaneous ureterostomy appears, from the data reported herein, to be a safe and effective means for urinary drainage in selected renal transplant recipients. It is feasible if the ischemic, normal-caliber ureters provided with all renal donor grafts are utilized, and it remains viable and patent, secondary to the neovascularity that develops in the distal nonfunctional loop. Our experience with this procedure in six cadaveric transplant recipients makes it the procedure of choice, as opposed to the use of an intestinal conduit, for urinary drainage of a transplanted kidney when the bladder is not available. It avoids the necessity of preparatory bowel surgery that has its attendant risk of peritoneal contamination and leak in an immunocompromised patient. The presence of chronic bacteriuria and the subsequent risk of urosepsis do not appear to detract from its usefulness.

Pentagastrin Stimulation of Human Colon Carcinoma

D. Byron McGregor, MD; Laura L. Morriss, PhD; Pacita B. Manalo, MD; Richard A. Bomberger, MD; Ronald S. Pardini, PhD

• This study examines the trophic effects of pentagastrin administration on the growth of transplanted human colon carcinoma in mice. Three different human colon carcinomas were implanted into dorsal subcutaneous pouches of BALB-C athymic mice—tumor A, COLO 320 DM undifferentiated carcinoma; tumor B, WiDr epithelial carcinoma; and tumor C, mucus-producing signet-ring cell adenocarcinoma from a patient volunteer. Tumors grew for four to six weeks and then groups were randomly assigned to receive either saline injections or pentagastrin, 2.0 mg/kg three times a day for 14 days before harvest. Tumors were homogenized and analyzed for DNA, RNA, and protein contents. Each tumor type showed a different biochemical pattern of response to pentagastrin stimulation. The data confirm that pentagastrin is trophic to human colon carcinoma and suggest a possible clinical role for hormonal manipulation.

(*Arch Surg* 1989;124:470-472)

Carcinoma of the colon remains the most prevalent and second most lethal internal malignancy of this society. Discouragingly, our therapeutic approaches have remained the same in substance and outcome for decades. While some other solid tumors, notably breast, thyroid, and prostate, have all been shown to respond to hormonal manipulation, no hormone or system of hormones has yet been demonstrated to be of therapeutic benefit in the treatment of this common neoplasm.

Over the last 15 years, the antral hormone, gastrin, has increasingly been shown to be a participant in the regulation of metabolic activities of the gut. In a series of articles[1-3] beginning in 1973, Johnson[2] demonstrated that gastrin is a trophic hormone to the mucosa of the colon as well as other sites along the gastrointestinal tract. In 1982, we demonstrated a stimulatory effect of both exogenous and endogenous gastrin on chemically induced colon tumors in rats.[4] Winsett et al[5] demonstrated a similar effect in transplantable murine tumors and demonstrated that the gastrin receptor antagonist, proglumide, was able to inhibit the growth of gastrin-responsive colon cancers.[6] Stimulation of growth of a human colon cancer has been performed in cell culture[7] but has yet to be applied clinically. Our project was designed to extend this physiology one step closer to the eventual clinical arena by studying the effects of the synthetic C-terminal pentapeptide, pentagastrin, on solid in vivo tumors of human origin.

MATERIALS AND METHODS

Three different human colon carcinomas were implanted into dorsal subcutaneous pouches of BALB-C athymic mice using methods previously described.[8] COLO 320 DM and WiDr human adenocarcinoma cell lines were used. The COLO 320 DM cells were maintained in RPMI 1640 medium with 10% fetal bovine serum, and the WiDr cells were maintained in Eagle's minimum essential medium with nonessential amino acids and 90% Earle's balanced salt solution with 10% fetal bovine serum. Approximately 10^6 cells from the fourth passage of each line were inoculated as single-cell suspensions into a subcutaneous pouch created 1 cm caudad to the scapula of each mouse using a 15-gauge needle. A third tumor, histologically classified as a mucinous adenocarcinoma, was harvested directly from a patient volunteer at the time of sigmoid resection. It was transported in iced buffered Hank's solution, sectioned into 1-mm cubes, and similarly implanted. Solid tumors were transferred a minimum of three times to assure sterility and viability of the tumor line.

Solid tumors from each of the three tumor lines were harvested, divided into 1-mm segments, and again implanted subcutaneously in 12 mice. The tumors were allowed to grow four to six weeks, at which time the animals were randomly assigned to control or experimental groups. Experimental animals received pentagastrin, 2.0 mg/kg subcutaneously at 12-hour intervals for 14 days. Control animals received similarly timed saline injections. Tumors were excised and stored in liquid nitrogen.

Tumors were homogenized in normal saline and assayed for DNA, RNA, and protein contents. The DNA and RNA were extracted and assayed according to the diphenylamine and orcinol methods of Schneider[9] using calf thymus DNA and calf liver RNA as standards. Protein was determined by the modified Lowry method of Ohnishi and Barr[10] using bovine serum albumin standard.

‡$P<.02$.

Statistical differences between group means for DNA, RNA, and protein were analyzed by Student's t test for small sample populations.[11] $P<.02$ was considered significant.

RESULTS

Each inoculation resulted in the formation of a solid tumor. Photomicrographs of harvested tumors (Fig 1) document the success of xenograft transfer. The COLO cell line is a moderately differentiated, highly secretory adenocarcinoma, originally obtained from the sigmoid colon of a 55-year-old woman and known to produce serotonin, norepinephrine, epinephrine, corticotropin, and parathormone. After transfer, the COLO (Fig 1, top) cell line retained its pleomorphic nuclei and abundant vacuolated cytoplasm demonstrating secretory activity. The WiDr cell line is a poorly differentiated epithelial adenocarcinoma known to produce carcinoembryonic antigen. With transplantation, the WiDr (Fig 1, center) cell line retained its epithelial homogeneity and nuclear hyperchromasia and pleomorphism. Its overlapping cells (cytologic feature) and occasionally irregular anaplastic lobulated nuclei (histologic feature) each confirm its rapid growth. Finally, after transplantation of the mucinous adenocarcinoma (Fig 1, bottom), it retained its morphologic features of eccentric nuclei, vacuolated cytoplasm, and high percentage of signet-ring–type cells consistent with slow growth and mucus production.

The results of biochemical analyses and the percentage increase in respective measurements of the pentagastrin-treated group are shown in the Table. Analyzed for DNA content, both epithelial cell types showed striking changes of from nearly double in the COLO cell line to nearly 12-fold in the WiDr cell line. The slow-growing mucinous xenograft showed no change. Likewise, analysis for RNA content showed considerably greater increases in the poorly differentiated tumors than in the signet-ring cell tumor. Analysis for protein content showed the nonsecretory WiDr to exhibit no change, while the mucus-secreting signet-ring cell xenograft and the highly secretory COLO cell line demonstrated significant increases.

COMMENT

Although vastly different in their responses, each cell line displays a profile of stimulated activity as characteristic as its histologic features (Fig 2). The COLO cell line (Fig 2, top left) seems to exhibit a more classic model of trophism—increased DNA production stimulating increased RNA production which stimulates increased protein production. The WiDr cell line (Fig 2, top right) displays an equally stimulated system of nucleotides that does not seem to result in increased protein production. Finally, the mucinous signet-ring cell xenograft (Fig 2, bottom) shows no change in its nucleotide contents but nevertheless mounts a significant increase in synthetic activity at least of protein.

These data generate as many questions as they answer. The nature and function of gastrin receptors that must control the enzymatic activity resulting in these changes have not been adequately delineated. The observation that different tumor lines display unique patterns of biochemical responses suggests that pentagastrin must act at multiple sites to control synthesis, degradation, or both. Furthermore, any clinical role for such stimulatory activity, even if predictable, remains speculative. We are, however, able to conclude that pentagastrin does exert a stimulatory effect on solid human colon cancers at least as described in this model. Finally, the response of different cancers is not uniform, but, rather, each tumor seems to respond biochemically in ways consistent with its biologic behavior and histologic features.

This work was supported by a grant from the Reno (Nev) Cancer Center.

Inhibition of the Stimulated Canine Exocrine Pancreas by Amino Acids and Fat

Richard S. Stubbs, MB, ChB, MD, FRCS, FRACS, Bruce E. Stabile, MD

• To investigate the possible exocrine pancreatic inhibitory actions of amino acids and fat, pancreatic fistula outputs and plasma concentrations of glucagon, somatostatin, and pancreatic polypeptide were measured in response to intravenous (IV) and intraduodenal nutrient administration in six dogs submaximally stimulated with cholecystokinin. Intravenous amino acids caused abrupt and significant 45% to 73% reductions in stimulated pancreatic protein, bicarbonate, and volume outputs. There were no significant associated changes in plasma hormone concentrations and no similar immediate pancreatic inhibition with IV mannitol, thus suggesting a possible direct inhibitory effect of amino acids. Intraduodenal amino acids and IV fat evoked no significant pancreatic output suppression. Intraduodenal fat rapidly caused significant 40% to 62% reductions in stimulated outputs that were associated with an 81% rise in plasma pancreatic polypeptide concentration, suggesting a gut-mediated inhibition. We conclude that IV amino acids and intraduodenal fat both inhibited stimulated pancreatic secretion but probably by different mechanisms.
(*Arch Surg* 1989;124:473-478)

Intraluminal amino acids and fat are known to be potent stimulators of exocrine pancreatic secretion through a complex mechanism presumed to involve the release of cholecystokinin.[1-3] These nutrients have also been shown to release significant quantities of glucagon, somatostatin, and pancreatic polypeptide—peptide hormones known to have pancreatic inhibitory capability—from the pancreas and gut.[4-6] If release of these peptides by amino acids and fat has relevance to regulation of pancreatic secretion, then some degree of pancreatic inhibition by intraduodenal (ID) administration of the nutrients would be expected. Although largely untested, this hypothesis is suggested by the finding that the maximal pancreatic enzyme response to ID amino acids or fat is only 50% to 70% of that to exogenous cholecystokinin.[2,3,7]

While the exocrine pancreatic response to intravenous (IV) amino acids is incompletely understood, the response to IV fat has scarcely been investigated. The 1979 report by Konturek et al[8] contending that both IV amino acids and fat stimulated pancreatic secretion has largely been contradicted.[9,10] Still other investigations have suggested an inhibitory influence of IV nutrients on the human and canine pancreas stimulated with secretin and cholecystokinin.[11,12]

To further clarify the inhibitory effects of amino acids and fat on the stimulated pancreas and to elucidate the mechanisms involved, we administered these nutrients IV or ID to dogs during submaximal stimulation with cholecystokinin. Pancreatic outputs together with plasma concentrations of glucagon, pancreatic polypeptide, and somatostatin were measured before, during, and after the period of IV or ID nutrient delivery.

MATERIALS AND METHODS

Experimental Protocols

Six adult mongrel dogs weighing between 16 and 23 kg were prepared with chronic gastric and pancreatic fistulas by a modification of the method of Herrera et al.[13] Experiments were commenced no sooner than three weeks following operation and were performed at intervals of not less than 48 hours. Food but not water was withheld for 18 hours prior to each test. Experiments were performed in duplicate in each dog. At the beginning of each experiment, the gastric cannula was opened and the stomach gently flushed with water. If food residue was encountered, the study was cancelled. If the stomach was empty, the gastric fistula was left open to drain freely for the duration of the study. Using a hind limb vein, the tip of a long polyethylene catheter (PE 50) was advanced to lie in the inferior vena cava for central IV infusion of nutrients or 0.15 mol/L of sodium chloride. Perfusion of ID nutrients or saline was accomplished via the hollow obturator of the Herrera cannula. Using peristaltic pumps (Harvard), IV and ID administration rates were kept constant at 100 mL/h.

In the control studies, cholecystokinin octapeptide (CCK-OP, Bachem Fine Chemicals, Torrance, Calif) was infused IV at 250 ng/kg per hour for three hours after an initial 30-minute basal period. This submaximally stimulating dose of cholecystokinin octapeptide was chosen after preliminary dose-response studies

consistently revealed failure to sustain pancreatic secretion at a constant output for three hours in response to a maximal stimulating dose of 500 ng/kg per hour. Cholecystokinin octapeptide was dissolved in 0.5% bovine serum albumin solution and delivered via a Y-shaped connector into the central venous catheter at 30 mL/h. Experiments were then repeated with the addition of an IV infusion or ID perfusion of either mixed amino acid solution (10% Aminosyn, Abbott Laboratories, North Chicago, Ill) at 10 g/h or fat emulsion (20% Liposyn, Abbott Laboratories, North Chicago, Ill) at 20 g/h during the second hour of cholecystokinin octapeptide infusion. The composition of the mixed amino acid test solution is given below:

Amino Acid	mg/dL
Alanine	1280
Arginine	980
Histidine	300
Isoleucine	720
Leucine	940
Lysine	720
Methionine	400
Phenylalanine	440
Proline	860
Serine	420
Threonine	520
Tryptophan	160
Tyrosine	44
Valine	800
Glycine	1280

The composition of the fat emulsion test solution was as follows:

Fatty Acid	mg/dL
Linoleic	15400
Oleic	2600
Palmitic	1400
Stearic	500

Saline was infused IV during ID nutrient perfusion and vice versa. Blood samples were drawn at 30-minute intervals for somatostatin, pancreatic polypeptide, and glucagon determinations by specific radioimmunoassays (RIAs) and for measurements of plasma-free amino acids or serum triglyceride concentrations. For this purpose, a heparinized venous access needle was maintained in a limb other than that used for the IV infusion.

Because of the high osmolarity of the amino acid solution infused IV (1000 mOsm/L), an additional control study was performed to determine the effect of a hyperosmolar solution on the stimulated pancreas. For this purpose, the same experimental protocol was followed but with the substitution of IV mannitol (1000 mOsm/L) at 100 mL/h during the second hour of cholecystokinin octapeptide infusion.

Measurements

Pancreatic juice was collected continuously and divided into ten-minute samples. The volume of each sample was determined to the nearest 0.1 mL. Bicarbonate concentration was measured by adding 1 mL of 0.1 mol/L of hydrochloric acid to 0.5 mL of each sample and back-titrating to a pH of 7.0 with 0.2 mol/L of sodium hydroxide. Total protein concentration, as a measure of total enzyme concentration, was estimated by measuring absorbance at 280 nm, using an autoanalyzer with a spectrophotometer (Beckman DM) and employing bovine serum albumin as standard. The outputs of bicarbonate and protein were calculated by multiplying volume by concentration.

For peptide RIA, blood was collected in edetic acid tubes to which aprotinin (Trasylol [FBA Pharmaceuticals, New York]) 500 Kallikrein inhibitor units/mL of whole blood was added. Samples were immediately centrifuged at 4°C for ten minutes at 2500 rpm. The plasma sample was then divided into thirds and stored at −20°C for future RIA. The glucagon, somatostatin, and pancreatic polypeptide assays were performed by methods previously described.[14-16] For determination of plasma amino acid concentration, blood was collected in dry heparinized tubes and immediately centrifuged at 4°C for ten minutes at 2500 rpm. One milliliter of plasma was then added to 1 mL of a solution containing 45 mg of sulfosalicylic acid, vortexed, and recentrifuged at 4°C for a further 20 minutes at 2500 rpm. The supernatant was stored at −70°C for subsequent amino acid measurement by an amino acid analyzer (Beckman). For serum triglyceride measurement, blood was collected into plain tubes and centrifuged for ten minutes at 2500 rpm. The serum was stored at −20°C for subsequent analysis by an enzymatic method.

Fig 1.—Pancreatic protein output of six dogs with chronic pancreatic fistulas in response to three-hour intravenous (IV) infusion of cholecystokinin octapeptide, 250 ng/kg per hour, without (control) and with simultaneous IV infusion of mixed amino acids (AA), 10 g/h, during second hour. In this and subsequent figures, each point represents mean and each vertical line represents SEM. Asterisk indicates significant difference from control value.

Data Analysis

Pancreatic secretion has been expressed as the mean ten-minute response for the 30-minute interval preceding the designated time. This was calculated from two studies per dog. The pancreatic secretion obtained during each 30-minute interval of the IV amino acid or fat (or mannitol) infusion study or the ID amino acid or fat perfusion study was compared with the secretion during the same 30-minute interval in the control study by an analysis of variance. The plasma concentrations of somatostatin, pancreatic polypeptide, and glucagon measured at the midpoint and end of the 60-minute IV infusion or ID perfusion of amino acids or fat were compared with the corresponding concentrations at the same times in the control study using analysis of variance. The number of dogs (five or six) was used for calculation. P value of less than .05 was taken to indicate a significant difference.

RESULTS

Control Study

Infusion of cholecystokinin octapeptide, 250 ng/kg per hour, caused significant pancreatic stimulation of protein,

Fig 2.—Pancreatic protein output of five dogs in response to three-hour intravenous (IV) infusion of cholecystokinin octapeptide, 250 ng/kg per hour, without (control) and with IV mannitol (1000 mOsm/L) at 100 mL/h during second hour.

Fig 3.—Pancreatic protein output of six dogs in response to three-hour intravenous infusion of cholecystokinin octapeptide, 250 ng/kg per hour, without (control) and with simultaneous intraduodenal (ID) perfusion of mixed amino acids (AA), 10 g/h, during second hour.

volume, and bicarbonate outputs. The control protein responses are shown in Figs 1 through 5. Despite a minimal and insignificant decline in the level of secretion over the three-hour study period, a high level of stimulation was maintained. Parallel responses were noted for bicarbonate and volume outputs. The infusion of cholecystokinin octapeptide caused progressive and significant rises in plasma pancreatic polypeptide and glucagon levels. In contrast, the modest rise in plasma somatostatin levels was not significant. These control responses are shown in Fig 6.

IV Amino Acid Study

The infusion of IV mixed amino acids resulted in significant inhibition of the cholecystokinin octapeptide–stimulated pancreatic protein output (Fig 1). Parallel results were also noted for outputs of bicarbonate and volume. Stimulated protein secretion was reduced by 45% after 30 minutes of the amino acid infusion ($P<.05$). Stimulated bicarbonate secretion was reduced by 73% and stimulated volume output was reduced by 60% during the same period ($P<.05$). At this point, the plasma amino acid concentration had risen 70% above the preinfusion concentration (from 2.06 ± 0.15 mmol/L to 3.51 ± 0.08 mmol/L). Within 60 minutes of stopping the infusion, plasma amino acid concentration returned almost to basal (2.23 ± 17 mmol/L) while pancreatic protein secretion partially recovered and subsequently declined again (Fig 1). Despite minimal rises in plasma glucagon, pancreatic polypeptide, and somatostatin concentrations during the amino acid infusion, there were no significant increases over the levels in the control study, including at 90 and 120 minutes, when pancreatic inhibition was maximal.

IV Mannitol Study

No inhibition of cholecystokinin octapeptide–stimulated pancreatic secretion was observed over the period of the mannitol infusion (60 to 120 minutes). However, a significant decline in protein output was noted during the final 30 minutes of the experiment (Fig 2).

ID Amino Acid Study

Introduction of ID amino acids caused no significant inhibition of the cholecystokinin octapeptide–stimulated pancreatic outputs of protein, bicarbonate, or volume compared with controls. However, pancreatic secretion did decline during the second 30 minutes of the perfusion and, in the case of protein, continued to decline after cessation of the perfusion (Fig 3). Plasma-free amino acid concentration rose throughout the period of ID perfusion and peaked at the termination of the perfusion (from 2.02 ± 0.21 mmol/L to 2.78 ± 0.25 mmol/L). Plasma somatostatin levels were essentially unchanged by the cholecystokinin octapeptide

Fig 4.—Pancreatic protein output of five dogs in response to three-hour intravenous (IV) infusion of cholecystokinin octapeptide, 250 ng/kg per hour, without (control) and with IV infusion of fat emulsion, 20 g/h, during second hour.

Fig 5.—Pancreatic protein output of five dogs in response to three-hour intravenous infusion of cholecystokinin octapeptide, 250 ng/kg per hour, without (control) and with intraduodenal (ID) perfusion of fat emulsion, 20 g/h, during second hour.

infusion alone or by the addition of ID amino acids. Plasma glucagon levels rose gradually throughout the study but were not significantly different from those at the corresponding time points in the control study. Plasma pancreatic polypeptide levels rose slightly but insignificantly above the control level at the conclusion of the ID perfusion with amino acids and subsequently returned to control levels.

IV Fat Study

No inhibition of pancreatic secretion was observed following IV infusion of fat emulsion (Fig 4) despite a dramatic rise in the level of circulating serum triglycerides (from 0.32 ± 0.02 mmol/L to 6.74 ± 0.62 mmol/L) in response to the infusion. Minimal rises were noted in plasma somatostatin, pancreatic polypeptide, and glucagon concentrations, but these were not statistically different from those observed in the control study with cholecystokinin octapeptide alone.

ID Fat Study

Perfusion of ID fat resulted in a 40% inhibition of the stimulated protein output from the cholecystokinin octapeptide–stimulated pancreas ($P<.05$) (Fig 5). Similar patterns of inhibition were noted for the stimulated bicarbonate and volume outputs with 52% and 62% reductions, respectively. The inhibition of pancreatic output began immediately after commencement of the ID fat perfusion, reached maximal degree at the end of the perfusion, and persisted with only minimal recovery throughout the remainder of the study. Serum triglyceride levels rose minimally and insignificantly only late in the study (from 0.26 ± 0.02 mmol/L to 0.34 ± 0.04 mmol/L). Intraduodenal fat perfusion did not alter plasma levels of somatostatin or glucagon in comparison to control values. In contrast, plasma pancreatic polypeptide concentrations rose after 30 minutes of ID fat perfusion, increased to 81% above control level after 60 minutes, and remained persistently elevated to the end of the study (Fig 6). While the mean pancreatic polypeptide responses above controls were large, the differences were not significant due to large variances.

COMMENT

The findings of the present study suggest that both mixed amino acids and fat are capable of exerting inhibitory as well as stimulatory effects on exocrine pancreatic secretion. However, while both nutrients caused significant 40% to 73% reductions in cholecystokinin octapeptide–stimulated outputs of protein, bicarbonate, and volume, the mechanisms of inhibition appear disparate.

The results for infusion of IV amino acids are in accor-

Fig 6.—Plasma levels of somatostatin (SLI), glucagon (GLI), and pancreatic polypeptidelike immunoreactivities (PPLI) in five dogs in response to three-hour intravenous infusion of cholecystokinin octapeptide, 250 ng/kg per hour, without (control) and with intraduodenal (ID) fat perfusion, 20 g/h, during second hour.

dance with the findings of DiMagno et al[11] and Saitoh et al.[12,17] Both the study of DiMagno et al and the present study demonstrate pancreatic inhibition paralleling the level of hyperaminoacidemia. It appears, however, that the degree of inhibition possible through this mechanism is limited. The maximal inhibition in the present study was noted after 30 minutes of amino acid infusion, notwithstanding a further rise in plasma amino acid concentration after 60 minutes. Only a slightly greater degree of inhibition was noted by Saitoh et al[12] following infusion of more than twice the load of amino acids. Similarly, DiMagno et al[11] infused protein hydrolysate IV into four volunteers at 24 g/h and observed only a 40% to 50% reduction in trypsin output evoked by the relatively weaker pancreatic stimulus of ID amino acids. The inhibition of protein output observed by us in response to IV amino acid infusion was biphasic. After cessation of the infusion and the subsequent fall in plasma amino acid concentration, there was a corresponding recovery of protein secretion. The subsequent decline in secretion at the end of the experiment may have been caused by fluid shifts resulting from the hyperosmolar infusate (1000 mOsm/L). This is suggested by the similar late inhibition imparted by infusion of mannitol (1000 mOsm/L) in the absence of significant inhibition during the actual infusion period.

While others[11,12] have suggested that glucagon release in response to hyperaminoacidemia was responsible for observed pancreatic inhibition, our results do not support this hypothesis. That glucagon is released in this experimental setting cannot be disputed, but the plasma levels achieved appear incapable of producing the degree of inhibition seen. DiMagno et al[11] found that after exogenous glucagon administration, the minimum plasma level that exerted pancreatic inhibition was 410 ng/L (approximately 117 fmol/mL), a level significantly higher than that detected in their study or in ours. Furthermore, our study for the first time has included an appropriate control study that indicates that cholecystokinin octapeptide infusion alone produces glucagon levels comparable to those caused by hyperaminoacidemia but without accompanying pancreatic inhibition. Although plasma pancreatic polypeptide and somatostatin levels also rose minimally in response to IV amino acid infusion, the changes were not different from those seen during the control study with cholecystokinin octapeptide alone. Thus, it would appear that the immediate inhibition of the cholecystokinin octapeptide–stimulated pancreas by IV amino acid infusion is not mediated by circulating glucagon, pancreatic polypeptide, or somatostatin nor is it related to the hyperosmolar nature of the infusate.

The present studies have failed to demonstrate a significant early inhibitory action of ID mixed amino acids on the stimulated exocrine pancreas. While confirmation of a modest release of pancreatic polypeptide by intraluminal amino acids coinciding with a slight decline in pancreatic secretion has been provided, little support for a modulating role of the circulating peptide in this setting can be offered. This is contrary to earlier findings in dogs given exogenous pancreatic polypeptide in doses producing smaller plasma increases than those evoked by a meal, which caused significant inhibition of pancreatic secretion stimulated by secretin plus cerulein.[18] The small decline in pancreatic secretion after 30 minutes of ID amino acid perfusion also coincided temporally with a significant hyperaminoacidemia and may reflect an effect of absorbed amino acids. We have presented evidence that minor inhibition of pancreatic secretion does follow absorption of intraluminal amino acids.[19] The more marked late decline in protein secretion 60 minutes after termination of the ID perfusion may represent inhibition imparted by release of a distal gut hormone such as peptide YY that is known to exert suppressive effects on pancreatic secretion.[20] While our studies showed no increases in circulating levels of glucagon or somatostatin following ID amino acid perfusion, previous reports employing selective visceral venous sampling or isolated perfused pancreatic preparations have documented somatostatin release under similar stimulation.[5,21] In eight human subjects, however, somatostatin administration at a dose producing levels similar to those measured after a meal did not affect pancreatic secretion stimulated by secretin and cerulein.[22]

The results of this study suggest that IV infusion of fat has no effect on stimulated pancreatic exocrine output. Despite a greater than 20-fold increase in serum triglyceride values, there were no differences from control levels of plasma glucagon, pancreatic polypeptide, or somatostatin. This lack of effect of IV fat is consistent with the findings of Matsuno et al[23] who studied five dogs and five postoperative patients with pancreatic fistulas. In both dogs and patients, IV infusion of a fat emulsion superim-

posed on pancreatic stimulation by combined secretin and cholecystokinin infusion exerted no consistent effects and no suggestion of significant inhibition.

Unlike amino acids, ID fat perfusion clearly did produce a significant degree of pancreatic inhibition. As this effect was evident immediately on initiation of the perfusion, a gut-mediated mechanism is suggested. Persistence of the inhibition after termination of the perfusion may reflect slow absorption of fat from the gut lumen. While there were no changes in plasma levels of glucagon or somatostatin relative to controls, there was a progressive though not quite significant rise above control levels of pancreatic polypeptide during and after ID fat perfusion. However, the level and duration of this increase was of sufficient magnitude to at least suggest a role in the observed inhibition by ID fat.

From these studies, we conclude that there are differential effects of IV and ID amino acids and fat on the cholecystokinin octapeptide–stimulated exocrine pancreas of the dog. Amino acids IV but not ID immediately inhibited stimulated pancreatic secretion by an unknown but possibly direct mechanism. In contrast, ID but not IV fat evoked pancreatic inhibition probably through a gut-mediated mechanism. It is possible that increased levels of pancreatic polypeptide subserved this role. Pancreastatin, a very recently discovered peptide from porcine pancreas with pancreatic exocrine inhibitory capability, may also be a candidate messenger in the gut-mediated mechanism.[24]

Surgical Care of Submental Gunshot Wounds

Karen H. Calhoun, MD; Spencer Li, MD; William D. Clark, DDS, MD; Charles M. Stiernberg, MD; Francis B. Quinn, Jr, MD

The care of patients with self-inflicted facial gunshot wounds is complex and challenging. The magnitude and self-inflicted nature of the injuries naturally give rise to questions about potential for successful rehabilitation. The surgical care and rehabilitation of ten such patients are described. The initial grotesque disfiguration belies the reasonable chances for functional restoration. Patients in this series who completed reconstruction swallow well enough to maintain body weight, speak understandably, breathe without tracheostomy, and have an appearance sufficiently normal that they can interact socially without embarrassment. Guidelines are proposed for multidisciplinary medical care leading to satisfactory functional, aesthetic, social, and psychiatric rehabilitation (*Arch Otolaryngol Head Neck Surg* 1988;114:513-519).

From the Department of Otolaryngology, University of Texas Medical Branch, Galveston (Drs Calhoun, Clark, Stiernberg, and Quinn), and the Department of Internal Medicine, Baylor College of Medicine, Houston (Dr Li). Dr Clark is now in private practice in Las Cruces, NM.

Detection of the Cancer-Prone Colon, Using Transepithelial Impedance Analysis

Richard J. Davies, MD; Renah Joseph; Horacio Asbun, MD; Marc Sedwitz, MD

• Alterations in ionic conductance may represent an early mitogenic signal; therefore, impedance analysis was used to examine differences in the electrical properties of the distal colon in a cancer-susceptible (CF_1) and a cancer-resistant (DBA) strain of mouse following administration of the carcinogen dimethylhydrazine. The electrical conductance of the surface colonic epithelium increased in CF_1 mice from a mean (±SEM) of 41.1±3.0 milliSiemens·cm^{-2} (mS·cm^{-2}) in controls to 52.6±3.1 mS·cm^{-2} following dimethylhydrazine treatment. The conductance decreased in the cancer-resistant DBA group from 154.6±44.1 mS·cm^{-2} in controls to 35.1±17.2 mS·cm^{-2} following dimethylhydrazine treatment. This difference in response to the carcinogen may partly explain differences in susceptibility noted between these two species. Epithelial impedance analysis may be of use in the early detection of the colon at risk for subsequent cancer development.

(*Arch Surg* 1989;124:480-484)

Despite improvements in surgical and radiation therapy, the mortality from large-bowel cancer has remained virtually unaltered during the past 50 years. Adjuvant chemotherapy has also failed to make a significant impact on survival so that approximately 58% of patients die of this neoplasm during the five years from the time of initial diagnosis.[1-4] Consequently, this neoplasm is the second most common cause of death from cancer in the United States and many Western countries.[4] These dismal survival statistics have led to renewed interest in primary and secondary prevention. Primary prevention of colorectal cancer would require the identification of etiologic factors and their removal from the environment. Secondary prevention using screening techniques to identify early cancers or their precursors such as polyps is neither cost-effective nor has the sensitivity or specificity to gain widespread acceptance.[5-9]

Although it is not clear when initiation occurs, many authorities agree that it may take decades before the malignant phenotype is expressed.[10,11] During this period promoting events influence the large-bowel mucosa and eventually result in the malignant transformation of one cell or a few cells that develop into a neoplasm. Although the existence of synchronous or metachronous cancers is a well-recognized phenomenon, it is difficult to understand why multiple tumors do not develop more frequently since there are billions of cells exposed to similar environmental and genetic influences.[12] A field defect probably exists in patients with large-bowel cancer indicating that the mucosa at risk is different from mucosa derived from patients not at increased risk for the development of cancer. Most of the studies demonstrating a field defect involve cell proliferation studies using in vitro labeling techniques.[13-19] These studies have been done in patients with a genetic predisposition to develop colorectal cancer, such as patients with familial polyposis or nonpolyposis familial colon cancer syndromes. However, even in sporadically developing colorectal cancer (the most common variety), histologic changes have been observed in the mucosa at sites distant to the cancer suggesting that a field defect exists.[20] An increase in DNA synthesis and tritiated-thymidine labeling has been demonstrated in the normal-appearing mucosa derived from patients with sporadic large-bowel cancer compared with mucosa derived from patients without the disease.[21] These differences are relatively slight and subject to the errors of observer interpretation. In addition, the techniques are labor intensive, probably precluding these methods as a screening tool, which could be used to identify the mucosa at risk for cancer development in the nongenetically predisposed patient.[20,21]

Multiple changes occur at the cell surface during growth stimulation and transformation,[22,23] such as alterations in cell surface glycoproteins, altered cell membrane permeability, altered ion fluxes, changes in cell-to-cell coupling, and alterations in the epithelial tight junctions.[24-29] These changes may occur in the mucosa at risk for subsequent transformation before the malignant phenotype has been expressed. Since the large-bowel mucosa mainly consists of an epithelial cell layer interspersed with occasional goblet cells, its electrical properties are primarily determined by the ionic permeability of the tight junctions and the surface epithelial cells. When the resistance is coupled with the capacitance properties of the surface epithelium, it forms a parallel resistor-capacitor circuit with a characteristic time constant equal to the product of R (resistor) and C (capacitor). The equivalent circuit in its simplest form has an additional resistor in series with the parallel resistor-capacitor to represent the electrical barrier provided by the underlying subepithelial layer and muscle. This equivalent circuit may be termed a *lumped model*, although more complex circuits representing the electrical properties of the bowel wall can be constructed as depicted in Fig 1. Therefore, it is possible to construct an electrical equivalent circuit analog of the epithelium made up of resistors and capacitors. The characterization of the electrical circuit may be accomplished by measuring the electrical impedance, which is the ratio of the measured voltage to a constant applied sinusoidal current at a given frequency. At each frequency two quantities are measured: the ratio of the magnitudes of the applied voltage to the measured voltage, and the normalized time delay of the voltage sinusoid compared with the current sinusoid (the phase angle ø). This relationship can be represented as a Nyquist plot and the impedance characteristics of the epithelium may be measured.[30,31]

We have used epithelial impedance analysis to examine the electrical properties of the distal colon taken from a susceptible mouse strain (CF_1) after administration of saline or the carcinogen dimethylhydrazine, which produces large-bowel cancer. The changes in impedance were compared with those occurring in a resistant strain of mouse (DBA) following identical treatment. It is suggested

Fig 1.—Resistor-capacitor analogs representing electrical characteristics of large bowel. Simple Lumped Model: R_p and C_p represent resistance and capacitance of surface epithelium, respectively; R_s, series resistance due to underlying nonepithelial layers and chamber resistance. Complex Lumped Model: Subscripts A, BL, J, and S denote apical, baso-lateral, tight-junctional, and series, respectively. Distributed Model: Subscripts L and LIS denote lateral cell membrane and lateral intercellular space, respectively. Otherwise subscripts are same as in complex lumped model (from Davies et al[33]).

that this technique, which measures the electrical characteristics of the surface epithelium, may be useful in the detection of the cancer-prone colon or rectum.

MATERIALS AND METHODS

Nonfasting adult female CF_1 or DBA/2 mice weighing between 18 and 22 g were used in all experiments and were maintained under identical conditions of cyclic 12 hours of light and dark. Regular chow (Ralston Purina Co, St Louis) and water were allowed ad libitum. The carcinogen dimethylhydrazine (Aldrich Chemical Co Inc, Milwaukee) was freshly prepared on the day of

Fig 2.—Derivation of impedance profile. Abbreviations, terms, and their derivations are explained in "Materials and Methods" section. ø indicates phase angle at maximum reactance; *l*, center of impedance locus with *x* equal to displacement of locus from *x*-axis; and *r*, radius of impedance plot (from Davies et al[33]).

injection and dissolved in 0.9% saline and injected subcutaneously into the groin in a dosage of 20 mg/kg weekly for four weeks. Following each weekly injection animals were kept in a negative flow hood for 12 hours to prevent atmospheric contamination. Control animals were subcutaneously injected with an identical volume of 0.9% saline.

One week after the fourth injection animals were killed using cervical dislocation and the colon was removed and rinsed with iced sodium-free Ringer's solution. Because preliminary studies have failed to demonstrate any difference in stability of the tissue whether the seromuscular layer was stripped, all experiments were performed on pieces of colon containing all layers, including the mucosa. Each distal segment of the colon was mounted within ten minutes in an acrylic chamber (area, 0.28 cm^2) and bathed on the mucosal and serosal side with equal volumes of sodium-free Ringer's solution at 37°C continuously oxygenated with 95% O_2 and 5% CO_2, maintained at a pH of 7.4, and circulated using a bubble-lift mechanism. The sodium-free Ringer's solution contained choline (which replaced Na), 140 mmol/L; K, 5.2 mmol/L; Ca, 1.2 mmol/L; Mg, 1.2 mmol/L; HCO_3, 25 mmol/L; HPO_4, 2.4 mmol/L; H_2PO_4, 0.4 mmol/L; Cl, 119.8 mmol/L; and glucose, 10 mmol/L. Sodium-free Ringer's solution was used because of previous observations that differences in the impedance profile were more evident in this solution following dimethylhydrazine treatment.[32,33]

Impedance measurements were made using two silver-silver chloride (Ag-AgCl) working electrodes and two Ag-AgCl measuring electrodes with one of each positioned on either side of the membrane. This configuration was chosen to avoid electrode polarization. A signal generator was used to excite the mucosa with a sine wave signal of adjustable frequency. The resultant voltage drop due to the bowel sample was compared with the voltage drop across an external adjustable load consisting of a parallel combination of a resistor and capacitor. When the comparison of these two signals yielded a "zero error," the tissue impedance was considered to be that of the external load. A constant driving voltage of 40 mV was used and the applied current varied between 30 and 60 μA. Pilot experiments confirmed that an identical Nyquist plot was obtained by measuring the impedance at 40 or 12 frequencies between 10 and 20 000 Hz, and therefore 12 frequencies were selected at 20, 50, 70, 100, 200, 500, 700, 1000, 2000, 5000, 7000, and 10 000 Hz. The resistance and capacitance were measured at each of these frequencies. Electrical stability of the tissue was noted for at least three hours, although a gradual decay of resistance and capacitance was observed during this period so that all experiments were performed at the same time to reduce temporally related errors. Further details of the methodology employed have been previously described.[32,33]

Values of resistance and capacitance were obtained at each of

the selected frequencies. The reactance was derived from the following formula:

(1) $$\text{Reactance} = 1/2\pi fC$$

where f is frequency in Hertz units and C is capacitance in farads.[30] The real portion of impedance (Z) was plotted against the imaginary portion using an iterative curve fit routine (Labtech Notebook, Laboratory Technologies Corporation, Wilmington, Mass). Using a simple lumped model in which the resistive and capacitive components of the bowel wall are represented as a resistor and capacitor in parallel and a further resistor in series with these two components (Fig 1), the impedance (Z) can be written in complex notation as follows:

(2) $$Z = R_s + (R_p/j\omega C_p)/(R_p + 1/j\omega C_p)$$

where j is the complex operator $(1)^{1/2}$, R_s is the series resistance, R_p is the epithelial resistance, C_p is the epithelial capacitance, and ω is the angular frequency. Separating real from imaginary parts is shown as follows:

(3) $$Z = R_s + (R_p)/(1 + \omega^2 C^2_p R^2_p) - j(\omega C_p R^2_p)/(1 + \omega^2 C^2_p R^2_p)$$

From Fig 2, which demonstrates the derivation of the impedance profile, it can be seen that

(4) $$R_0 = R_p + R_s = R_t$$

and

(5) $$R_\infty = R_s$$

where R_0 and R_∞ are the resistance of the tissue at zero and infinite frequency, respectively, R_t is the total resistance of the tissue and R_pC_p may be represented as the time constant T. Equation 3 may be rewritten as follows:

(6) $$Z = [R_\infty + (R_0 - R_\infty)/(1 + \omega^2 T^2)] - j\{[\omega T(R_0 - R_\infty)(1 + \omega^2 T^2)]\}$$

In this equation the first part of the equation is the real component R (resistance) of the colon impedance and the second part of the equation represents the reactance (reactive capacitance) in the xy plane. The reactive and real terms are functions of Z and ω. When the frequency was varied between zero and infinity, Z changed continually along the curve in the xy plane of the graph (Fig 2). This curve is almost a perfect semicircle although for the purpose of illustrating the derivation of the impedance profile, it has been distorted in the figure and is known as an impedance plot. Elimination of ω and T from equation 6 yields the expression for the impedance plot in the xy plane of Fig 2.

(7) $$\text{Reactance} = (R_0 - R_\infty)\,[R_0 - R)/(R_c - R_\infty)^{1/2}]\,[(R_0 - R_\infty)/(R - R_\infty)]$$

Equation 7 was used in the curve fitting program to determine R_0 and R_∞. The highest point on the curve is the maximum capacitive reactance of the tissue. This analytic expression for the impedance plot derived the impedance measurements for each piece of tissue and are summarized in the Table. The other impedance characteristics such as phase angle ø, characteristic frequency, characteristic capacitance, and resistance were calculated from these values using the planar trigonometry outlined in Fig 2.

An F test was used to examine the variance of each set of measurements derived from the impedance profiles obtained in each experimental group. Dimethylhydrazine-treated animals were compared with saline-treated controls using an unpaired Student t test as appropriate.[34] Two-tailed t tests were used in all instances. A statistically significant difference was considered probable when $P<.05$.

RESULTS

Bowel resistance and capacitance were measured at different frequencies to develop an impedance profile then plotted as a Nyquist plot for each tissue, from which the impedance characteristics were derived for each piece of colon. The Table summarizes the impedance characteristics of four groups of animals. The electrical conductance of the surface colonic epithelium increased in CF_1 mice from a mean (±SEM) of 41.1. ±3.0 milliSiemens·cm^{-2} (mS·cm^{-2}) in controls to 52.6±3.1 mS·cm^{-2} ($P<.02$) following dimethylhydrazine treatment. Conductance decreased in the cancer-resistant DBA group from 154.6±44.1 mS·cm^{-2} in controls to 35.1±17.2 mS·cm^{-2} ($P<.001$) following dimethylhydrazine treatment.

The Nyquist plots of the colons demonstrated the dependence of the reactance and resistance on the frequency of the applied sine wave. Although slight elevation or suppression of the impedance locus "x" was observed in most specimens, all impedance plots were close to a semicircle. Phase angle ø has been considered to be the most accurate impedance measurement in demonstrating alterations in the electrical characteristics of an epithelium,[35,36] and in this study in the susceptible CF_1 strain it decreased by 28%. Conversely the phase angle ø increased by more than 280% in the susceptible DBA strain following dimethylhydrazine administration.

R_∞, which is the series resistance of the epithelium, increased by about the same amount in the two groups of animals following dimethylhydrazine treatment. However the increase in epithelial conductance noted in the susceptible strain of CF_1 mice is due mainly to the smaller relative increase in R_0 compared with R_∞ following dimethylhydrazine treatment. Although R_∞ increased by a similar amount in the DBA strain following dimethylhydrazine treatment, a much greater increase in R_0 was noted which explains the decreased value of conductance following dimethylhydrazine treatment. A significant increase in the characteristic frequency was noted in both strains of mice following dimethylhydrazine treatment, although only the susceptible CF_1 strain underwent an increase in characteristic capacitance compared with the decrease noted in the resistant DBA strain.

COMMENT

In this study we have demonstrated differences in the electrical properties of the bowel wall induced by a colonic carcinogen dimethylhydrazine in a susceptible (CF_1) and resistant (DBA) strain of mouse, both of which have been extensively studied as animal models of large-bowel cancer.[37,38] To our knowledge, the reason for the differential susceptibility noted between these two species is unknown. It was thought that resistant strains might be unable to metabolize the carcinogen dimethylhydrazine to its active form methylazoxymethanol, although recent experiments have demonstrated that direct administration of the active metabolite methylazoxymethanol failed to produce proliferative changes or cancers in DBA mice.[39]

These experiments were performed in a sodium-free Ringer's solution and therefore changes in sodium transport or permeability cannot explain these carcinogen-induced changes in impedance. We have previously reported that dimethylhydrazine induces an increase in Na^+/H^+ exchange in CF_1 but not DBA mice.[40] This has

*P value is derived from the unpaired Student *t* test comparing dimethylhydrazine-treated animals with controls; NS indicates not significant; n, number of animals; R_o, resistance at zero frequency; R_∞, resistance at infinite frequency; R_c, characteristic resistance of the tissue (these three values are non–area corrected); reactance, capacitive reactance of the tissue at the characteristic resistance; G, epithelial conductance corrected for area in milliSiemens·cm⁻²; Phase ø, phase angle; x, deviation of the impedance locus from the *x*-axis with a positive value indicating elevation and a negative value indicating suppression; r, radius of the impedance profile; F_c, characteristic frequency; T, time constant; W, time constant; and Cap_c, capacitance at the characteristic frequency and resistance.

also been recently demonstrated in rat colonic brush-border vesicles following dimethylhydrazine adminstration.[41] The impedance changes noted in the present study may represent changes in the tight junctions between cells or alterations in membrane fluidity.[41] One of the earliest changes induced by mitogens is an increase in cell membrane conductance[24]; this may represent a mitogenic signal leading to increases in cell proliferation.[22] Malignant transformation has been associated with loss of tight junction integrity[23,24] so that cells lose contact inhibition and pile up on one another. An increase in membrane ionic permeability or loss of tight junctional integrity would cause an increase in transepithelial conductance observed in the CF_1 mice in these experiments. Alternately, down regulation of membrane conductance or increased cell-to-cell adherence would be expected to produce the type of impedance changes noted in the DBA mice in these experiments. Further experiments using intracellular measurements will be required to separate the relative contributions of the cell membrane or the tight junctions to this phenomenon. It is of interest that the resistant DBA strain was not unresponsive to the dimethylhydrazine but underwent considerable changes in impedance in an opposite manner to the changes induced in the CF_1 mice; this suggests an adaptive response rather than unresponsiveness.

Preliminary studies from our laboratory have demonstrated that the impedance profile of large bowel from patients with a cancer is different when compared with bowel from patients without evidence of a malignant neoplasm (data not shown). Although it may be thought that the "normal" bowel at a distance from a bowel cancer is histologically normal, several studies have suggested alterations in crypt cell kinetics and structure even in the mucosa at a site remote from the primary malignant neoplasm.[20,21] This is especially true in patients with familial polyposis and familial colon cancer syndrome[13-16]; however, major differences in the uninvolved mucosa from patients with sporadic colon cancer have yet to be identified to our knowledge. It was noted that the conductance properties of the mucosa taken at least 5 cm from the index cancer were lower than in controls. The reduction in conductance was somewhere intermediate between the increase seen in the CF_1 mouse and the decrease seen in the DBA mouse. This may suggest that human colonic mucosa is of intermediate susceptibility when compared with a susceptible and resistant animal model of large-bowel cancer.

Although one must exercise caution before extrapolating animal data to humans, alterations in impedance may help diagnose susceptible individuals who have undergone initiation and are likely to develop cancer under the right promoting influences. It is possible that the normal-appearing mucosa has been exposed to the same carcinogenic or genetic influences as the mucosa giving rise to the index cancer although it has not yet undergone malignant transformation. The multistep hypothesis of carcinogenesis would suggest several events in the development of cancer with perhaps a lead time of several decades before a cancer actually develops.[10-12] If the initiating and early promotional events affect the entire mucosa, then alterations in the characteristics of the mucosa in the cancer-prone colon would have important screening and therapeutic implications.[42]

Whether altered impedance represents alteration in cell surface signaling within the epithelial layer or changes in the cytoskeletal structure cannot be determined. The capacitance properties of a complex layer of cells such as the bowel wall are thought to reside in the true epithelial layer.[36] We have not observed alterations in the capacitance properties by stripping away the underlying serosa and muscle layers. Therefore, it can be concluded that since the observed alterations take place in the frequency domain, these differences are epithelial in origin. Although we have previously noted alterations in sodium transport and transmural depolarization in a murine model of colon cancer, we have failed to observe an increase in the resistance of the bowel wall.[40,43,44] This may be because the previously employed methodologies using voltage clamp techniques have not been able to separate the resistance of the surface epithelial cells from the underlying layers. As can be seen from the Table, the resistance of the true epithelial layer only constitutes about 10% to 20% of the total resistance of the bowel wall. Therefore, it may not be possible to identify alterations in the resistance of the epithelial layer using these other techniques not employing capacitance measurements. These changes begin even before histologic evidence of dysplasia occurs and are

progressive with increased doses of the carcinogen administered over a longer period of time.[32]

Since an alteration in ionic flux has been proposed as an early mitogenic signal[22,45,46] during growth stimulation or transformation, the alteration in epithelial impedance characteristics identified in this study may represent changes in ionic conductance following initiation. Whether altered ionic permeability represents a mitogenic signal or a nonobligatory event in the malignant process cannot be determined; however, the need for better screening methods for large-bowel cancer is apparent.[47-49] Present methods are plagued with insensitivity and nonspecificity.[5-9] Currently it is impossible to identify which patients should undergo frequent colonoscopy or contrast studies because of difficulty in assessing risk and identifying groups of patients who have already undergone initiation. Earlier diagnosis would appear to be of key importance in preventing death from this common malignant neoplasm.[50-52] Identification of the mucosa at risk before the malignant phenotype is fully expressed may be possible using epithelial impedance analysis to identify the cancer-prone large bowel. Whether this biophysical approach has a role toward this goal remains to be determined from more extensive studies.

This investigation was supported in part by the Research Services of the Veterans Administration and by a gift from American Mediscan Inc, Los Angeles.

The mice used in this investigation were provided by Charles River Breeding Laboratories Inc, Wilmington, Mass.

Recent Trends in the Management of Incisional Herniation

Raymond C. Read, MD, PhD, Gordon Yoder, PAC

• There is a high incidence of risk factors for incisional herniation in hospitalized veterans. Almost half the defects appear more than 12 months after celiotomy. "Buttonholing" of the rectus sheath by a sawing motion of the continuous nonabsorbable suture may be responsible for this later herniation. Suturing with synthetic, slowly absorbed monofilament may reduce delayed herniation. The recurrence rate after primary repair was 24.8% (n=206), and after a second repair the recurrence rate was 41.7% (n=36). Plastic prostheses, used only in difficult cases (18% of the sample), were associated with a recurrence rate similar to that associated with sutures because of protrusion around the edge. The use of larger and better fixed ("sandwich") polypropylene mesh (Marlex) is indicated. Subxiphoid epigastric hernias following sternotomy do not require prosthetic herniorrhaphy.

(*Arch Surg* 1989;124:485-488)

Over the past decade, there has been a renewed appreciation of the seriousness of wound breakdown after closure of abdominal incisions. Since 2 million celiotomies are performed annually in the United States, the potential problem is considerable. Catgut had been shown to be associated with an unacceptably high rate of dehiscence.[1] This is not surprising, since healing takes three to four months and since these stitches have lost most of their tensile strength by two weeks. Concern over this experience has delayed the acceptance of new synthetic sutures that are more slowly absorbed through hydrolysis unaffected by sepsis. Norris[2] (1939) and Jones et al[3] (1941) found that evisceration and dehiscence could be reduced from 11% to 1% without the need for tension sutures, if mass "near-to-far" suturing was used rather than layered repair. To avoid suture granulomas, incisional pain, and wound sinuses, the use of "man-made" monofilament (nonabsorbable) continuous sutures has become widely accepted because of speed and the fact that tension is more evenly distributed.[4] The peritoneum does not need to be closed as a separate layer.[5]

Unfortunately, although dehiscence has been all but eliminated, incisional herniation has not, occurring in up to 44% of cases.[6] Whereas suture breakage, knot slippage, and protrusion between stitches no longer play important roles, extrusion of sutures due to excessive tension does. To reduce this hazard, replacement of large defects with a prosthesis has been used increasingly since the introduction of woven polyethylene in 1958[7] and knitted autoclavable nonfraying polypropylene mesh (Marlex) in 1962.[8] Despite these advances, incisional herniation continues to be seen, sometimes years after the scar should have stabilized.[9] A new type (subxiphoid) has been described following heart surgery.[10] To study the present dimensions of this problem, a retrospective analysis of an unselected consecutive experience over the past decade was carried out.

METHODS

The records of patients undergoing an incisional hernia repair in the John L. McClellan Memorial Veterans Hospital, Little Rock, Ark, between 1977 and 1987 were gathered and reviewed. Some patients had their original celiotomy or incisional herniorrhaphy at other hospitals. Efforts were made to obtain pertinent information from these referring institutions. For each individual, data were arranged into five categories: personal details (eg, age and weight), the operation preceding herniation (site and type of incision), the incisional hernia, the repair, and follow-up. *Wound infection* was defined as discharge of pus up to one month postoperatively. Assessment of wounds was carried out in the clinic at intervals of 1, 3, and 6 months, or one year. Palpable knots, defects, protrusions, and pain were documented. An attempt was made to contact all living patients. *Incisional herniation* was defined as a palpable defect or defects greater than 1 cm in diameter and in close proximity to the scar, through which bulging was either palpable or visible when patients coughed or raised their legs from the examination couch. Patients who were aware of their hernias were asked when they had first been noticed. These data, along with information obtained at physical examination, defined the *appearance time*.

A consecutive series of 232 patients were operated on for incisional hernia. Twenty died (none within 30 days of their repair), and six were unavailable for follow-up. The remaining 206 comprised the study population. One hundred thirty-two patients continued to live locally and were seen in clinic. Seventy-four had to be contacted by telephone and questionnaire. There was only one woman in the group.

Mass closure with either interrupted or, more recently, continuous, nonabsorbable No. 1 monofilament (Prolene [far-to-near stitches]) was the basic technique used for laparotomies over the ten-year period. A similar repair was performed for incisional herniation (sutured); relaxing incisions in the rectus sheaths were sometimes added. If the surgeon considered the defects too large or too numerous for stitches, a single plastic prosthesis (almost always Marlex) was inserted either as an inlay or, more frequently, as an onlay. An attempt was made to cover the bowels with peritoneum or omentum, and the remaining abdominal wall was treated as a single layer after the peritoneal sac had been removed where indicated. The peritoneum was opened and adhesions were removed if the hernia was incarcerated or loculated or if there had been a history of abdominal colic; occasionally, inadvertent entry into the peritoneal cavity or the bowel occurred. Intraperitoneal placement of a Marlex graft was used if necessary because other workers had found it to be eminently satisfactory.[11] Operations were performed by residents under staff supervision. Suction

Fig 1.—Appearance time of incisional and recurrent incisional hernias.

drainage was used in a minority (12%), mainly if a large prosthesis had been inserted. Patients received prophylactic intraoperative and short-term postoperative treatment with antibiotics (usually a cephalosporin or a penicillin, unless some other drug was indicated).

RESULTS

Two hundred six patients aged 26 to 90 years (average, 58.3 years) underwent a primary incisional hernia repair; 169 (82%) were sutured, and in 37 (18%) a plastic prosthesis was also used. The appearance time for the incisional hernia subsequent to the initial laparotomy was one to 332 months (median, 28.3 months). At one year 56.1% were present, at two years 71.1% were present, at three years 79.4% were present, and at five years 86% were present (Fig 1). Overall, 41 (19.9%) of 206 patients had wounds that were infected after the initial operation; the incidence varied with the site from zero (left upper quadrant) to 50% (left lower quadrant) (Table). Only eight repairs were grossly infected; in three of these the Marlex had to be removed. Even though the bowel was entered to remove adhesions in 11 cases (5.0%), the overall infection rate was only 3.9%, which is about twice our rate for elective, noncontaminated abdominal surgery and much below the rate at initial laparotomy (19.9%). Most of the patients were overweight (87% to 159% of ideal body weight [average, 117.8%]). Seventy-one (34.4%) of these individuals had had multiple abdominal operations before herniation. The procedure leading to herniation had been an emergency operation in 64 (31.1%); trauma was a precipitating event in 18 (8.7%). Six patients had had a gastric bypass procedure for morbid obesity. Forty-six patients had had cholecystectomy (25 in the right upper quadrant and 21 epigastric). Twenty-one patients had had operations on the aorta. In eight, the original operation was for ventral herniation (umbilical). There were 30 instances of incarceration (14.6%) and five cases of strangulation (2.4%). Eleven of the 206 patients had suffered major dehiscence requiring reoperation, secondary closure, or skin grafting after the original laparotomy. Hernia size averaged 4.1×6.2 cm^2. The defect tended to be larger in midline herniation and after recurrence. The average size of Marlex graft was 7×10 cm^2. There were 51 recurrences (24.8%), including three dehiscences. The recurrence rate in the sutured group was 24.3% (41/169), and the recurrence rate with a plastic prosthesis was 27% (10/32).

The most common site of the incisional hernias was midline (153 of 206 [74.3%]). Twenty-six of these 153 followed wound infection as follows (Fig 1): subxiphoid, ten (6.5%); epigastric, 89 (58.2%); periumbilical, 40 (26.1%); and hypogastric, 14 (9.2%). The original operation usually was on the stomach, colon, aorta, gallbladder, pancreas, or spleen (Fig 2). Sixty-four (31.1%) were emergency procedures. Of the epigastric and periumbilical hernias, 24 of 131 were multiple; most of them were buttonhole hernias[12] (58%), ie, multiple, small, eccentric hernias, in the rectus sheaths. All the patients with subxiphoid hernias had had cardiopulmonary bypass and open heart surgery, usually for coronary artery disease.[9,10] They had been repaired with interrupted, nonabsorbable synthetic sutures. The

Incidence of Wound Infection Preceding Incisional Herniation

Site of Incision	n	No. (%) With Wound Infection

Total	**206**	**41** (19.9)

Fig 2.—Distribution of original surgical procedures.

Fig 3.—Gradual sawing through ("buttonholing") of myofascial defects by continuous nonabsorbable monofilament suture.

Fig 4.—A, Limited fixation of knitted polypropylene mesh (Marlex) to edge of defect. B, Sandwich repair giving good lateral fixation.

second most common site of herniation was the right upper quadrant, with lesions occurring in 25 (12.1%). Almost all of these hernias followed cholecystectomies, most of which were emergency procedures. Thirteen hernias in the right lower quadrant (6.3%) followed urgent appendectomy. Five hernias in the right flank (2.4%) and five in the left flank (2.4%) followed operations on the kidney or aorta or for trauma. (A few were at drain sites, sometimes coupled with right-upper-quadrant or midline hernias.) Hernias in the left lower quadrant were seen after sigmoid colostomy or retroperitoneal approaches to the iliac vessels. The one lesion in the left upper quadrant followed a splenectomy.

Of the 51 patients whose incisional hernia recurred, 36 were reoperated on: 16 were sutured, and 20 received Marlex grafts (55.6%). Their body weight was 93% to 159% of ideal weight (mean, 125.6%). Fifteen (41.7%) of these 36 reoperations failed: seven with sutures (43.8%) and eight with Marlex (40%). Ten of 15 patients had a second operation for recurrent incisional herniation; three (30%) failed. Two of six were sutured and one of four received Marlex. All three with failed procedures had a third operation for recurrence. They were sutured, and none recurred. Recurrent incisional herniation appeared earlier than primary (Fig 1). At one year 68.4% were present, at two years 78.9% were present, at three years 84.2% were present, and at five years 89.4% were present.

COMMENT

There are only a few long-term studies of large unselected series of patients with this common but neglected problem. Until recently, follow-up was terminated at one year, as the scar was considered to be stable by six months. However, Akman[13] reported in 1962 that only 68% of incisional hernias were noted by one year. Ponka[14] reported 77%. Prospective data from Europe in the past five years have documented[15,16] that only a little more than half of incisional hernial defects can be identified within 12 months. Further, a significant number, albeit mainly small and asymptomatic, continue to appear even after five years. A similar delayed manifestation of such defects was observed in the present study. Recurrent incisional herniation appeared sooner than primary. The lag in manifestation of these protrusions was originally blamed on observer error because of the masking effect of obesity, along with a lack of symptoms. Preplaced radio-opaque clips[17] or computed tomographic scanning[18] have been shown to assist in the diagnosis of small protrusions. However, Ellis et al[16] did not find a relationship between obesity and delayed herniation. They also could not confirm another hypothesis, ie, deep-seated infection.[19] An alternative, more plausible mechanism was suggested by the observation of buttonholes in the rectus sheath caused by a sawing motion of the nonabsorbable sutures[12] (Fig 3). This suggestion is consistent with our results in that many of these late defects were small, multiple, and eccentric to the midline scar. Now that longer-lasting synthetic sutures of proved absorbability are available,[4] it may be that their use will reduce late buttonholing. However, Ellis et al[16] reported delayed herniation after procedures with both kinds of sutures. More information is needed.

Incisional herniation is common in a population of hospitalized veterans because they have almost all the known risk factors for this entity. These risk factors and their incidence in our population of veterans are as follows:

Risk Factor	Incidence, %
Male sex	99.5
Age>60 y	47
Obesity	118-126 ideal body weight
Smoking	96
Alcoholism	20
Multiple laparoscopies	34
Incisions>18 cm	48
Trauma	18
Other emergencies	31
Cancer	19
Wound sepsis	20
Surgeons in training	100
Midline incision	74
Diabetes	10

Thus, the patients affected by incisional herniation are usually men, the incidence in men being three times that in women. The patients smoke heavily and have severe coughs due to chronic obstructive pulmonary disease. A number are alcoholics with abdominal distention, malnutrition, cirrhosis, and ascites. Many suffer from trauma or delay treatment until urgent surgery is necessary. Atherosclerotic cardiac or vascular disease is common, requiring open heart surgery or operation on the aorta with attendant long incisions. Many of these patients are elderly and have had abdominal surgery for cancer (particularly for cancer of the larger bowel), ulcers, or gallbladder disease. Most are overweight, some to such an extent that gastric bypass has been required. Finally, these patients are operated on by surgeons in training whose supervision is many times lax, since incisional hernia repair (like other herniorrhaphies) is often regarded as a trivial procedure.

An important risk factor common to all series of incisional herniation is wound sepsis. The infection rate following celiotomy has been reported as high as 80%.[20] Pollock et al[21] believed that this predisposing cause could be reduced to great effect. Our infection rate of slightly less than 20% is considerably lower than that in many reports. Particularly gratifying is the low infection rate of 3.5% after repair, even though a few wounds were contaminated with bowel contents and a plastic prosthesis was inserted in a minority. Short-course antibiotic coverage may well have contributed. Lewis[22] made a similar comment after finding an infection rate of 4% in difficult cases treated with Marlex, his rate being almost identical to ours.

As in other series, every attempt was made to repair these defects without inserting a large foreign body (ie, a plastic prosthesis). The fairly high recurrence rate after simple suturing (24%) could argue in favor of the use of Marlex. Instead of using Marlex in one fifth of our cases, perhaps a third should have had this material inserted. The use of Marlex was associated with an initial recurrence rate of 27%, which is higher than the rate after simple suturing. However, the rate after suturing likely would have been higher had we continued to use sutures since failure rates of 44% have been reported under these circumstances.[6] As in other reports, we also found that failure occurred above, below, or beside the prosthesis. (Rupture through the Marlex mesh has yet to be described.)

In too many cases the whole scar had not been dissected out to rule out multiple or eccentric protrusions, the body wall had not been dissected back laterally far enough in front and back, or the prosthesis had been too small. Even when all these pitfalls are avoided, a critical problem may ensue if the Marlex mesh is not overlapped sufficiently externally and internally at its attachment to the cleared rim of the defect. Usher[23] emphasized the importance of this maneuver (Fig 4), and we recently have adopted Rubio's[24] technique originating from the same city (Houston). Thirty years ago the problem of lateral fixation of the prosthesis was identified.[7] It remains and needs to be tackled vigorously. Since tension necrosis is avoided and better lateral fixation can be obtained, we prefer inlay (if necessary, intraperitoneal) to onlay placement, as did Usher and more recent investigators.[25]

Midline abdominal incisions continue to be the most common site of herniation. The incision is popular and is almost uniformly used in emergency procedures, which have a high rate of contamination. We were surprised how frequently cholecystectomy was performed on these veterans, even though they were almost all men. Presumably this prevalence reflects one of the diseases of aging. Almost one half of these procedures were performed with a midline incision rather than the Kocher incision. Others[26] have commented on the high risk of incisional herniation when biliary surgery is conducted from the midline rather than the right upper quadrant. Aortic operations, a number of which were performed on the patients in our sample with vascular disease, require long xiphoid to pubis exposure, adding to the risk of herniation. Vascular disease affecting the coronary arteries has brought on a new type of epigastric hernia: the subxiphoid. This hernia occurs despite interrupted sutures of nonabsorbable monofilament and an absence of infection. An eccentric abdominal component of the sternal split has been recommended to avoid this sequela. Our experience differs in that plastic prosthesis was unnecessary for successful repair.[10]

NOW AVAILABLE

THE COMPLETE GUIDE TO PEDIATRIC SURGICAL DIAGNOSIS AND TREATMENT

Color Atlas of Pediatric Surgery

by **Peter S. Liebert, MD, FACS, FAAP**
Assistant Clinical Professor of Surgery
Columbia University
College of Physicians and Surgeons
New York

New!

537 Full-Color Figures!

This beautiful and comprehensive four-color atlas is the perfect clinical reference for all those who must know about pediatric surgical problems.

Color Atlas of Pediatric Surgery covers problems amenable to surgical intervention most often seen in infants and children. Stressing significant anatomical and functional problems in pediatric surgery, and techniques for solving these problems, the book covers the diagnosis, preoperative care, surgery, and postoperative management of conditions seen in patients ranging from the premature newborn to the adolescent.

- 745 figures, 537 in full color
- Comprehensive coverage of significant problems in pediatric surgery
- Actual clinical situations as they appear to the operating surgeon
- Step-by-step illustrations of surgical procedures and operative techniques
- Clear color photographs of surgical lesions

Contents:

Foreword • Preface • General Considerations in Pediatric Surgery • Skin and Subcutaneous Tissue • Face, Head, and Neck • Chest • Hernias and Defects of the Abdominal Wall • Upper Gastrointestinal Tract • Colon and Rectum • Liver, Spleen, and Pancreas • Urinary Tract • Genitalia • Solid Tumors • Trauma and Child Abuse • Index

1989 287 pages 745 figures 537 in color 0-444-01328-8 $175.00

Biochemical Adaptation of Venous Patches Placed in the Carotid Circulation

Dean M. Govostis, MD; Dennis F. Bandyk, MD; Thomas M. Bergamini, MD; Jonathan B. Towne, MD

• The influence of venous patching on luminal prostacyclin (PGI_2) and thromboxane A_2 (TBX) production of endarterectomized arteries was studied in a canine model. Fifteen dogs underwent bilateral common carotid endarterectomies. In each dog, one artery was closed primarily and the contralateral artery was closed by vein-patch angioplasty. At six and 12 weeks after operation, luminal prostanoid production from the venous patch, adjacent endarterectomized artery, and control artery and vein was measured by radioimmunoassay for 6-keto-prostaglandin $F_{1\alpha}$ and thromboxane B_2. Venous patches underwent "incomplete" biochemical adaptation with decreased luminal production of PGI_2 compared with control and endarterectomized arteries. Thromboxane production from venous patches was increased compared with normal vein but similar to control and endarterectomized arteries. At six weeks, PGI_2 production of vein-patched arterial segments was increased compared with arteries closed primarily. These data indicate that vein-patch angioplasty favorably influences surface thrombogenicity of healing, endarterectomized arteries and support its use in reparative carotid surgery.

(*Arch Surg* 1989;124:490-493)

The routine use of vein-patch angioplasty during carotid endarterectomy has been recommended by a number of authors to reduce the incidence of restenosis and minimize thrombogenicity of the endarterectomized segment.[1-3] Preference for this method of vessel closure following endarterectomy is based on concepts that, compared with primary closure, suture stricture is less likely to occur with vein-patch closure, vessel enlargement minimizes restenosis produced by the predictable circumferential myointimal hyperplasia that develops after operation, and the vein-patch endothelium may favorably influence healing of the endarterectomized artery. Whether these characteristics of vein-patch angioplasty are applicable in improving the functional patency of carotid endarterectomy in humans is unknown, since the mechanisms are based on limited experimental evidence in animals.

Placement of autologous vein grafts in the arterial circulation results in predictable changes in morphology and luminal prostanoid production termed "arterialization."[4-6] In a canine model of carotid artery healing following endarterectomy, we found venous patching did not influence patency or the rate and pattern of endothelial regeneration.[7] In both vein-patched and primarily closed arteries, endothelial regeneration was incomplete at two to three weeks after operation and complete by four to five weeks. An interesting observation of the study was that less severe intimal thickening was observed to develop in the vein patches compared with the healing endarterectomized artery wall. These findings suggested that the fate of venous patches in the arterial circulation may differ from that of vein grafts. A varied adaptation to "arterialization" can result from differences in surgical trauma and hemodynamics of vein-patch arterial segments compared by venoarterial grafting.[8-10]

Although the precise mechanisms by which vascular endothelium resists thrombus formation remain largely unknown, the production and luminal release of prostacyclin (PGI_2) by endothelial cells result in potent inhibition of platelet aggregation, an important initial step in arterial thrombus formation. Arterialized vein grafts demonstrate functional (biochemical) adaptation, which includes an increase in luminal PGI_2 production in addition to the well-known morphologic changes of thickening, fibrosis, and subendothelial myointimal cell proliferation.[6,11] The purpose of this study was to examine the biochemical adaptation of venous patches placed in the carotid circulation. Using our previously described canine model of carotid endarterectomy,[7] we serially measured luminal production of PGI_2 and thromboxane A_2 (TBX) from vein patches, adjacent healing endarterectomized artery wall, and normal carotid artery and external jugular vein after operation. In addition, the influence of venous patching on the biochemical recovery of endarterectomized carotid arteries was studied by comparing luminal prostanoid production in vein-patched artery segments with arteries closed by continuous suture.

Fig 1.—Template incubation chamber designed for measurement of vein patch and vessel luminal surface production of prostacyclin and thromboxane A_2; 4 × 10-mm elliptical hole exposes 36 mm² of luminal surface for assay.

MATERIALS AND METHODS

Canine Model

Fifteen adult mongrel dogs of either sex (weighing 24 to 30 kg) underwent bilateral common carotid endarterectomies. The dogs were anesthetized with 30 to 40 mg/kg of intravenous pentobarbital sodium, intubated, and placed on mechanical ventilation. On induction of anesthesia, cefazolin sodium (25 mg/kg) was given intravenously. Using sterile technique and ×2.5 optical magnification, the left external jugular vein and bilateral common carotid arteries were carefully dissected over a distance of 8 cm. The external jugular vein was excised using "no touch" technique and placed in a cold, heparinized lactated Ringer's solution (100 U/mL). Following systemic heparinization (100 U/kg), the common carotid arteries were occluded with vascular clamps and an endarterectomy was performed on each, over a 3-cm segment of the artery through a 4-cm arteriotomy. A cleavage plane was developed in the media using a scalpel, allowing excision of the entire intimal layer and inner attached media. The arteriotomy of the left carotid artery was closed with a continuous monofilament of 7-0 polypropylene suture. The right carotid artery was closed with a 4-mm–wide external jugular vein patch using continuous 7-0 suture. Intraoperative pulsed Doppler spectrum analysis was used to assess the operative site for technical errors based on changes in the center-stream blood flow patterns.[12,13]

At two time intervals following endarterectomy (six and 12 weeks), the common carotid arteries were excised and patency was determined. These periods after operation were selected based on reports demonstrating that canine vein graft arterialization, in terms of increased PGI_2 production, occurs ten weeks following placement in the arterial circulation.[6,11] Luminal surface production of PGI_2 and TBX was measured only in patent arteries. Nine dogs were reoperated on after six weeks and the remaining six dogs after 12 weeks. No heparin was administered before vessel excision. Assays for control native vein prostanoid production were performed at both time intervals after operation by excision of the previously unoperated-on right external jugular vein. Control native artery levels were determined from proximal segments of previously undissected common carotid artery. Luminal prostanoid production was also measured from two sites (midpoint and end point) of the vein-patch itself, and healing endarterectomized carotid arteries were closed by continuous suture or vein-patch angioplasty. All dogs received humane care in compliance with the *Guide for the Care and Use of Laboratory Animals*.[14]

Radioimmunoassay Preparation and Methods

Excised external jugular vein and common carotid artery segments for radioimmunoassay of 6-keto-prostaglandin $F_{1\alpha}$ (6-keto-$PGF_{1\alpha}$) and thromboxane B_2, the stable metabolites for PGI_2 and TBX, were immediately rinsed with Hepes buffered saline (25 mmol/L, pH 7.5) to remove adherent blood elements and opened longitudinally. Vein-patched arterial segments were transected at the midpoint of the patched segment before opening the vessel along its longitudinal axis to permit exposure of both the venous patch and the endarterectomized artery lumen for prostanoid production measurements. Specimens were placed in a custom-designed template incubation chamber apparatus (Fig 1). Each 4 × 10-mm elliptical hole in the upper plate formed an incubation chamber that exposed 0.36 cm² of lumen surface for assay of 6-keto-$PGF_{1\alpha}$ and thromboxane B_2 production according to the method of Weksler et al.[15] A 0.25-mL aliquot of TRIS–sodium chloride buffer (15 mmol/L, pH 8.6) was pipetted into the incubation well for two minutes, quickly transferred to a polypropylene centrifugation tube, and then frozen at −20°C. A second incubation was then performed using TRIS buffer containing 20 μmol/L of arachidonic acid (AA) for stimulated PGI_2 measurements.

Luminal surface synthesis of PGI_2 was measured for both basal and AA-stimulated conditions by radioimmunoassay of tritiated

Fig 2.—Histogram of mean basal 6-keto-prostaglandin $F_{1\alpha}$ (6-keto-$PGF_{1\alpha}$) production at six weeks (diagonally striped bars) and 12 weeks (cross-hatched bars) after endarterectomy from control vein and artery (six- and 12-week measurements combined), vein patch, and endarterectomized arteries closed primarily or by vein-patch angioplasty. Values for *P* derived from Mann-Whitney *U* test for continuous data.

6-keto-$PGF_{1\alpha}$. Thromboxane B_2, the stable metabolite of TBX, was similarly determined by radioimmunoassay of tritiated thromboxane B_2. Standard curves were constructed for each assay using known amounts of labeled 6-keto-$PGF_{1\alpha}$ and thromboxane B_2, respectively. Prostanoid release values are expressed as nanograms per two minutes per 0.36 cm^2 of lumen surface.

Data Analysis

All data are expressed as mean ± 1 SEM. Differences in prostanoid levels between the various vessel segments were analyzed by the Mann-Whitney *U* test to avoid assumptions regarding the distribution of the data. A *P* value below .05 was considered significant.

RESULTS

Eleven (73%) of 15 common carotid arteries closed primarily were patent at the time of excision compared with all 15 arteries closed with vein-patch angioplasty ($P<.05$; χ^2 with $df=4.6$). Occluded carotid arteries were found in two of the study dogs undergoing reoperation at both the six- and 12-week follow-up intervals. Doppler flow analysis of center-stream blood flow patterns did not demonstrate severe flow disturbance proximal to, in the midpoint of, or distal to endarterectomized segments. Decreased blood flow velocity compared with primarily closed arteries and regions of flow separation (spectral broadening during late systole with flow reversal in early diastole) were identified in vein-patched arterial segments both at the primary operation and before excision. All patent carotid arteries after opening longitudinally had intact, glistening luminal surfaces without adherent thrombus by visual inspection.

Mean values for luminal production of basal and stimulated 6-keto-$PGF_{1\alpha}$ are given in the Table for native vein and artery, vein patches, and endarterectomized carotid arteries closed primarily and by vein-patch angioplasty. Basal values are also depicted graphically in Fig 2. Basal and stimulated levels measured in native vessels (control vein and artery) were similar at both intervals after operation. Assay of basal PGI_2 synthesis of normal carotid arteries was significantly higher than native venous levels ($P<.0005$). Stimulated venous and arterial production of 6-keto-$PGF_{1\alpha}$ were both significantly higher than basal levels ($P<.001$). Vein patches produced levels of 6-keto-$PGF_{1\alpha}$ that did not differ from native venous levels at both six and 12 weeks after operation. Compared with native artery levels, vein patches produced significantly less PGI_2 ($P<.005$). Endarterectomized arteries closed by vein-patch angioplasty produced basal levels of 6-keto-$PGF_{1\alpha}$ similar to native artery levels at both intervals after operation. In contrast, endarterectomized carotid arteries closed primarily had significantly less PGI_2 than control and vein-patched arteries at six weeks under both basal and stimulated conditions ($P<.01$). By 12 weeks, PGI_2 levels produced by primarily closed arteries were increased compared with levels measured in native and vein-patched arteries.

The mean basal levels of thromboxane B_2 synthesis measured from identical vessel segments used in the PGI_2 measurements are given in the Table. Normal and healing endarterectomized carotid arteries produced more thromboxane B_2 than normal veins ($P<.05$). At both six and 12 weeks after operation, vein patches placed in the carotid circulation produced increased thromboxane B_2 levels compared with native veins ($P<.005$).

COMMENT

Venous patches when placed in the carotid circulation as a vein-patch angioplasty appear to undergo "incomplete" biochemical adaptation in terms of PGI_2 synthesis. Basal levels of luminal PGI_2 release were less than native artery levels at 12 weeks after translocation, remaining similar to native vein levels. Vein-patch endothelium was responsive to maximal substrate enhancement (AA stimulation) but to levels less than native vein and artery. These findings differ from observations of arterialized canine vein grafts placed in both the femoral and carotid artery circulations.[6,11] Vein graft endothelial PGI_2 production increased to arterial levels at 12 weeks after operation but demonstrated no response to AA stimulation. This biochemical behavior was observed in vein-patched arterial segments without severe abnormalities in center-stream blood flow pattern. We had previously observed that if vein-patch endothelium was preserved and medial necrosis was minimized following transposition into arterial circulation, early (four- to five-week) intimal thickening of the venous transplant was avoided. The less severe morphologic changes observed in venous patches compared with venoarterial grafts in canine models suggest severity of vein harvest trauma may play a more important role than exposure to arterial pressure and hemodynamics in the biochemical adaptation involving prostanoid metabolism.

Our finding of decreased PGI_2 production from arterialized venous patches agrees with the observations of Bush et al[8,16] for in situ vein grafts and Eldor et al[9] for jugular veins placed in the carotid circulation after six weeks. The in situ grafting technique, which is associated with minimal vein wall surgical trauma, resulted in chronically arterialized vein grafts that produced PGI_2 levels lower than native artery produced, higher TBX levels compared with native veins, and less severe morphologic abnormalities of the flow surface than in excised, reversed venoarterial grafts. It is unknown whether the increased prostanoid production (PGI_2 and TBX) of arteries compared with veins, observed in this study and by other investigators,[6,9,11] represents intrinsic differences in biochemical capability of the endothelial cells or adaptation to the difference in hemodynamic environments (pressure, wall tension, shear stress, oxygen tension) to which the endothelial cells are exposed. Further study of healed endarterectomized segments closed by vein-patch angioplasty using techniques that localize and quantitate endothelial cell proliferation (tritiated thymidine labeling with autoradiography) is necessary to correlate biochemical adaptation of venous transplants with acute and chronic endothelial cell injury. It is unknown whether the increased PGI_2 production of arterialized vein grafts reflects or retards the development of myointimal hyperplasia universally observed in these substitute arterial conduits.

The presence of an intact and functionally normal endothelium is important in resisting platelet–vessel wall interaction and thrombus formation. This study and patency data pooled from our prior report document increased patency with vein-patch closure (96%) in this canine model of carotid endarterectomy compared with primary closure (71%) of the endarterectomized arterial segment ($P<.01$; χ^2 with $df=6.5$). It should be noted that endarterectomy site patency in this model was very sensitive to technical factors, including avoidance of deep media cleavage plane with exposure of adventitial elements, meticulous closure of the arteriotomy to minimize suture stenosis, and intravenous administration of heparin.[17]

In this canine model, endothelialization of the endarterectomized segment occurred by migration from the endarterectomy end points and suture line, with the rate and pattern similar in patched and unpatched vessels.[7] Endothelial regeneration was completed by five weeks, although

scattered areas void of endothelial cells were commonly found by scanning electron microscopy in arteries closed by either method. The present study confirmed that return of normal luminal PGI_2 synthesis lags behind reendothelialization of the endarterectomized segment. Despite endothelial coverage by four to five weeks after operation, basal and stimulated levels of PGI_2 similar to native arteries were not produced until 12 weeks after operation. At six weeks, PGI_2 production of arteries closed primarily was less compared with arteries closed by vein-patch angioplasty ($P<.01$). This delay in return of normal biochemical function was probably related to variation in the extent or stability of endothelium regeneration in primarily closed arteries. Blood flow patterns recorded both in primarily closed and vein-patched arteries at six and 12 weeks after operation did not vary appreciably from those observed at the primary operation. Blood flow velocity was increased in primarily closed arteries compared with vein-patched arteries and not associated with regions of boundary layer separation and flow reversal uniformly observed in dilated portions of the vein-patch angioplasty. These differences in blood flow between patched and unpatched vessels may influence the biochemical recovery of regenerated endothelium.

The patency and luminal prostanoid synthesis data of this study suggest that vein-patching angioplasty favorably influences surface thrombogenicity of healing endarterectomized arterial segment. Venous patches provide an endothelial cell–lined flow surface that resists thrombus formation and has a luminal PGI_2 synthesis capability similar to native veins. In addition, vein-patch angioplasty, by altering anatomy, hemodynamics, and the biochemical arterial environment, promotes earlier return of normal PGI_2 synthesis by the endarterectomized artery wall. These benefits of venous patching are probably most important in the immediate postoperative period, when thrombogenicity of the endarterectomized wall is highest. The biochemical benefit of vein-patch angioplasty may be blunted by the increased TBX released observed from vein-patch luminal surfaces. Thromboxane A_2 is one of the most potent stimulators of platelet aggregation and release action and is also a strong vasoconstrictor. Platelet activation initiates the coagulation cascade as well as the release of smooth-muscle cell mitogens that facilitates cellular proliferation.[18,19] Since all blood elements, especially platelets, produce TBX, the increased synthesis observed from the luminal surface of arterialized venous patches may have been related to platelet aggregation on the endothelium rather than release by perturbed endothelial or modified endothelial structures such as smooth-muscle cells or fibroblasts. The increased TBX levels of venous patches combined with platelet aggregation on traumatized endothelium support the use of antiplatelet therapy in the perioperative period to inhibit platelet aggregation and release mechanisms.

The decision to use venous patches in carotid surgery is commonly based on the intraoperative appearance of a small-diameter internal carotid artery or operative attempts to prevent stenosis in vessel repair. Prior investigation has documented that vein-patch angioplasty will increase vessel diameter and prevent the development of early circumferential intimal thickening.[7] Whether these benefits also occur when venous patches are used in peripheral graft revision or anastomotic stenosis due to intimal hyperplasia has not been examined. This study suggests that despite incomplete biochemical adaptation of venous patches placed in the carotid circulation, in terms of PGI_2 production, vein-patch angioplasty does favorably influence the arterial environment with regard to patency and normalization of PGI_2 synthesis by regenerated endothelium. These attributes support an increased role for venous patching in carotid endarterectomy to improve the functional patency of this arterial reconstruction.

Original Article

Limitations to Donating Adequate Autologous Blood Prior to Elective Orthopedic Surgery

Lawrence T. Goodnough, MD; J. Wasman; Kathleen Corlucci; Ann Chernosky

• We reviewed 175 patients who predeposited autologous blood prior to elective orthopedic surgery to define potential limitations of procuring adequate autologous blood. These potential limitations include physician underordering, storage interval, and erythropoietic response. We found that a continuing medical education intervention increased the amount of autologous blood requested by physicians for storage: from 121 U for 50 patients (mean = 2.4) before CME to 195 U for 65 patients (mean = 3.0) afterward; eight (16%) of 50 patients had 4 U or more requested before CME vs 25 (38%) of 65 patients afterward. Continuing medical education had no impact on mean (± SD) effective storage interval, 22.6 ± 9.0 vs 21.6 ± 9.4 days. Thirty (17%) of 175 patients were deferred (hematocrit ≤0.34) and were unable to donate units of blood requested; of these, 13 (43%) received homologous blood compared with 19 (13%) of 145 not deferred. We conclude that a significant percentage of patients are deferred from autologous donation because of hematocrit limitations and receive homologous blood. This problem is not related to physician underordering or inappropriate physician transfusion behavior, but rather to the erythropoietic response to serial phlebotomy over a limited storage interval. Future studies should focus on mechanisms to maximize autologous blood procurement.

(*Arch Surg* 1989;124:494-496)

Preoperative autologous blood donation (ABD) before elective surgery is a desirable clinical practice encouraged by a number of organizations such as the American Medical Association,[1] the American Association of Blood Banks,[2] the National Institutes of Health Consensus Conference on Acquired Immunodeficiency Syndrome,[3] and the American Red Cross.[4] Potential benefits of transfusion with autologous blood have been cited that include the following: it is the "safest" form of blood transfusion[5]; it represents a potential source of blood for both the national blood inventory and hospital-scheduled elective surgical procedures[6,7]; and it has a salutary effect on physician transfusion behavior.[8] We have previously shown that an ABD program can be an effective method of improving physician transfusion behavior. This salutary effect, however, was accompanied by insufficient procurement of autologous blood to minimize subsequent homologous blood transfusion.[8] In this study, we evaluated our ABD program to define the potential limitations of procuring adequate autologous blood and to assess the impact of a continuing medical education (CME) program on these limitations.

METHODS

Autologous Preoperative Blood Deposit Program

The University Hospitals of Cleveland Component Therapy Unit currently procures approximately 1000 U of blood from 400 elective surgical patients yearly. Approximately 70% of these patients undergo elective orthopedic procedures.[8] Guidelines established by the American Association of Blood Banks (AABB) for autologous blood storage[9] are followed. The number of units to be procured is determined by each patient's surgeon. Ferrous sulfate, 325 mg to be taken three times daily by mouth, is prescribed for every patient. Units are stored as whole blood in citrate-phosphate-dextrose-adenine with a 35-day outdate.

Audit

One hundred seventy-five consecutive patients who predeposited autologous blood and who were scheduled for elective orthopedic procedures from July 1, 1985, to Aug 15, 1987, were studied. Fifty consecutive patients in the ABD program scheduled for elective orthopedic procedures before (series 1, July 1, 1985, to June 30, 1986), 65 consecutive such patients after (series 2, Feb 26, 1987, to May 31, 1987) a CME intervention (below), and 60 such patients seen subsequently (series 3, June 1, 1987, to Aug 15, 1987) were audited by reviewing blood bank, component therapy, and medical records. The following data were recorded: units of autologous blood requested for storage; blood units stored; storage interval; recorded hematocrits (HCT); deferrals for inadequate HCT (≤0.34)[9] or other reasons; and transfusions subsequently received (units of autologous and homologous blood). The distribution of orthopedic procedures in the 175 patients is shown in Table 1. The three series of patients in this study were not different when analyzed for patient age, sex, and surgical procedure.

CME Intervention

One of us (L.T.G.) gave a 50-minute lecture presentation, "To Transfuse or Not to Transfuse," the content of which included risks of homologous blood exposure,[10-12] benefits of preoperative autologous blood storage,[13] issues of informed consent and quality assurance relevant to red blood cell transfusion,[14,15] acceptance of intraoperative and postoperative normovolemic anemia,[16] effect of our ABD program on physician transfusion behavior,[8] potential

limitations that result in inadequate storage of autologous blood with special emphasis on the desirability of storing as much blood as possible during our 35-day storage interval[9]; and the logistics of arranging autologous storage for patients at our institution. The CME program consisted of seven presentations: Surgery Grand Rounds (Sept 13, 1986), Medicine Grand Rounds (Sept 29, 1986), Anesthesia Grand Rounds (Oct 29, 1986), Gynecology Grand Rounds (Feb 13, 1986), Orthopedic Grand Rounds (Feb 14, 1987), Plastic Surgery Grand Rounds (Feb 14, 1987), and Head and Neck Surgery Grand Rounds (Feb 28, 1987).

Statistics

Differences in means were evaluated by the Student *t* test for data of parabolic distribution. The Mann-Whitney *U* test was used to compare data of nonparabolic distribution.

RESULTS OF THE CME INTERVENTION

Storage Intervals

Evaluation of 50 consecutive orthopedic patients in the ABD program before (series 1) and 65 consecutive patients after (series 2) the CME intervention revealed no impact on mean (±SD) storage intervals (time from first unit drawn to surgical date): 22.6±9.0 days vs 21.6±9.4 days. The time from last unit donated to surgical date also was not different: 8.7±5.5 days vs 7.5±4.0 days. Storage intervals were not related to whether patients had an HCT[10] deferral from phlebotomy in either series 1 patients (24.6±8.2 days [deferred] vs 22.1±9.3 days [nondeferred] or series 2 patients (24.9±12.8 days vs 20.8±8.4 days).

Autologous Blood Units Requested

The number of autologous units requested by surgeons for storage significantly increased after the CME intervention. One hundred twenty-six units were requested for 50 patients (series 1, mean=2.4) before CME intervention compared with 195 U for 65 patients after CME intervention (series 2, mean=3.0); eight (16%) of 50 patients were requested to store 4 U or more prior to CME compared with 25 (38%) of 65 after CME ($P<.05$).

Homologous Blood Transfused

As shown in Table 2, units of homologous blood transfused to patients able to predonate the requested number of autologous units declined significantly: from 12 (28%) of 42 in series 1, to six (11%) of 52 in series 2, to one (2%) of 51 in series 3 ($P<.05$). There was no such decline in homologous blood exposure in patients unable to donate the amount of autologous blood requested: five of eight patients in series 1, four of 13 patients in series 2, and four of nine patients in series 3. Thus, CME intervention toward physician transfusion practice significantly affected subsequent homologous blood exposure in patients who were able to predonate the amount of autologous blood requested by their physicians, but not in patients unsuccessful in predonating adequate autologous blood. The consequences of understoring autologous blood in patients undergoing elective orthopedic surgery are also shown in Table 2. Of 30 patients who were deferred and unable to store the requested units of autologous blood, 13 patients (43%) subsequently received homologous blood; this is compared with 145 patients who successfully predonated the requested amount of autologous blood, of whom 19 (13%) received homologous blood ($P<.05$). Chart audit of patients receiving homologous blood indicated that transfusion in almost all circumstances (16 of 17 patients) was appropriate.

Table 2.—Homologous Blood Exposure in Patients Undergoing Elective Orthopedic Surgery

	7/85-6/86 Series 1 (N=50)	2/87-5/87 Series 2 (N=65)	6/87-9/87 Series 3 (N=60)	Total (N=175)
Patients able to donate requested units	42	52	51	**145**
Subsequent homologous exposure	12	6	1	**19** (13%)*
Patients unable to donate requested units	8	13	9	**30**
Subsequent homologous exposure	5	4	4	**13** (43%)*

*$P<.05$.

Table 3.—Subsequent Homologous Exposure Is Not Related to Physician Underordering

	No. of Patients	Subsequent Homologous Exposure, No. (%)

≥4 U requested	35	3 (8.6)
Patients unable to donate requested units	**30**	13 (43)*
≤3 U requested	7	4 (57)
≥4 U requested	23	9 (39)

*$P<.05$.

Autologous Patients Deferred From Phlebotomy

Six of 175 patients were deferred from phlebotomy for reasons other than HCT limitation; none of these patients subsequently received homologous blood transfusion. Thirty (17%) of 175 patients in the combined series were unable to store the units requested because of low HCT (≤0.34) by AABB standards.[9] The initial HCT at first phlebotomy was significantly lower in these patients than in those not deferred: 0.38±0.03 vs 0.43±0.03 ($P<.001$). Twenty of the 30 deferred patients were female. Deferral was related to the number of autologous units requested (Table 3): seven (6%) of 117 patients in whom 3 U or less were requested were deferred compared with 23 (39%) of 58 patients in whom 4 U or more were requested ($P<.05$). Of 30 patients who were deferred and unable to store the requested units of autologous blood, seven patients were asked to predonate 3 U or less; four of seven patients subsequently received homologous blood. Twenty-three

patients were asked to predonate 4 U or more; nine of 23 received homologous blood (no different). In 145 patients able to donate the requested units of autologous blood, 110 were asked to give 3 U or less; 16 (14%) of 110 patients subsequently received homologous blood. Thirty-five patients were asked to give 4 U or more; three of 35 received homologous blood (no different). Thus, subsequent homologous blood exposure was related to whether patients successfully stored the requested number of autologous units and was not related to the number of autologous units requested for storage (ie, physician underordering).

COMMENT

Autologous preoperative blood deposit programs have received widespread support from the medical community[1-4] because of the potential benefits for patients, blood inventory, and physician transfusion behavior.[5-8] A previous multicenter study has shown that ABD is underutilized[13]; this underutilization can be improved with a coordinated program involving hospital blood banks, information services, and physicians.[6] Nevertheless, we have previously shown that patients predeposit insufficient autologous blood to minimize or eliminate their subsequent exposure to homologous blood.[8] Potential problems limiting sufficient autologous blood procurement include physician underordering, limitations of the storage interval, and erythropoietic response to phlebotomy.

Continuing medical education is perhaps the most traditional approach toward altering physician practice. In this study, we have shown that CME can correct the problem of physician underordering and profoundly reduce subsequent homologous blood exposure in patients who successfully store the amount of autologous blood requested by their physicians, from 12 (28%) of 42 in series 1, to six (11%) of 52 in series 2, and to one (2%) of 51 in series 3. Continuing medical education had no impact on the effective storage interval during which blood can be collected and inventoried for elective surgery. The consistency of the limitation of the erythropoietic response to serial phlebotomy over an effective storage interval is seen in Table 2, where the percent of patients deferred and unable to donate the requested units remains unchanged in each series of patients: eight (16%) of 50, 13 (20%) of 65, and nine (15%) of 60, respectively.

Table 3 illustrates that homologous blood exposure is not related to physician underordering. Fifty-eight patients were asked to donate 4 U or more; 23 (40%) were deferred and nine (39%) of 23 subsequently received homologous blood. This is compared with seven (6%) of 117 patients deferred when asked to donate 3 U or less with four (57%) of seven subsequently receiving homologous blood. We have thus demonstrated that when an autologous predeposit program is accompanied by an intervention, homologous blood exposure is related to donor deferral rate rather than physician underordering or inappropriate transfusion behavior.

The erythropoietic response to mild anemia (HCT $\geq$0.34) is clearly inadequate to avoid autologous donation deferral in 30 of 175 patients overall and in 23 of 58 patients asked to store 4 U or more. Thus, future studies of autologous predeposit programs should focus on the erythropoietic response as a limitation to procuring adequate autologous blood. Erythropoietic response to phlebotomy is a third limiting factor in procuring sufficient autologous blood to minimize the need for homologous blood exposure. The AABB standards have guidelines for elective autologous blood preoperative deposit that include a hemoglobin value of no less than 110 g/L or a packed cell volume of no less than 34%, and phlebotomy no more frequently than every three days and not within 72 hours of surgery.[10]

Erythropoietic response to serial phlebotomy is limited by functional iron availability and bone marrow response to erythropoietin. In our series, 20 of 30 deferred patients were female (compared with 83 of 145 of the nondeferred patients); this supports a role for iron availability and/or circulating blood volume as limitations. Others have shown that a significant number of normal community blood donors, especially women, are iron deficient and respond to iron therapy.[17] Even though patients in our ABD program are asked to take iron, noncompliance with ferrous sulfate has been well described[18] and the possibility of a functional iron limitation must be considered in some of these patients. Endogenous erythropoietin-induced bone marrow response as a limitation in procuring adequate autologous blood prior to elective orthopedic surgery is the focus of a current multi-institutional study.[19]

In conclusion, we have shown that (1) a significant percentage of patients are deferred because of HCT limitations and they subsequently receive homologous blood; (2) CME corrects physician underordering and reduces homologous exposure in patients who are able to store the amount of blood requested; and (3) storage interval remains a limitation for procuring adequate autologous blood before elective surgery. Future studies in ABD programs should focus on mechanisms to maximize blood procurement.

Clinical Note

Adenocarcinoma Arising in an Ileostomy

Report of Two Cases and Review of the Literature

Patricia L. Roberts, MD; Malcolm C. Veidenheimer, MD;
Sharon Cassidy, RN, ET; Mark L. Silverman, MD

• Adenocarcinoma arising in an ileostomy is rare. Two cases are reported, one of a 58-year-old woman and the other of a 54-year-old man who had each undergone a colectomy for chronic ulcerative colitis. Seven other cases previously reported in the literature are reviewed. Though the exact pathogenesis is uncertain, several possibilities, particularly with regard to antecedent dysplasia and backwash ileitis, are discussed. Routine yearly follow-up and examination of the stoma by a physician or enterostomal therapist may lead to earlier detection of this rare complication.
(*Arch Surg* 1989;124:497-499)

Stomal complications have been reported in 30% to 86% of patients undergoing conventional ileostomy.[1,2] These include necrosis, retraction, prolapse, parastomal herniation, obstruction, fistula, skin irritation, improper construction, and poor location. A rarely reported complication is adenocarcinoma arising in the ileostomy. We describe two such cases and review the seven cases previously reported in the literature.

REPORT OF CASES

CASE 1.—A 58-year-old woman presented to the Lahey Clinic Medical Center, Burlington, Mass, in late 1986 with an ulcerated area along the inferior pole of the ileostomy. At the age of 13 years, she had experienced bloody diarrhea and weight loss and was diagnosed as having ulcerative colitis. Six years later, in 1947, a proctoscopic biopsy of a sigmoid polyp revealed adenocarcinoma, and she underwent left hemicolectomy and proctectomy. Pathologic studies at the time revealed chronic ulcerative colitis as well as adenocarcinoma arising in a polyp with no evidence of involvement in any lymph nodes. She did well until the age of 24 years, when she had a flare-up of ulcerative colitis and underwent right hemicolectomy and Brooke ileostomy. Review of the microsections of the resected specimen of colon by one of us (M.L.S.) confirmed the presence of chronic ulcerative colitis and backwash ileitis with no evidence of dysplasia. However, review of the resected specimen of polyp was thought to indicate severe dysplasia and not invasive cancer.

Accepted for publication Jan 29, 1988.

No further complications were apparent until one month before admission, when she began to have difficulty with adherence of the ileostomy appliance. On examination, she was a well-nourished woman. Abdominal examination revealed no masses or hepatomegaly. A large ulcerated area was observed on the inferior portion of the ileostomy, and a biopsy revealed adenocarcinoma. Results of laboratory studies were normal, including a hematocrit level of 0.39, normal serum electrolyte levels, and a serum carcinoembryonic antigen value of 1 ng/mL (normal, 0 to 5 ng/mL).

The patient subsequently underwent en bloc excision of the ileostomy and anterior abdominal wall and transposition of the stoma to the left lower quadrant. The abdominal wall defect was closed with synthetic (Marlex) mesh. Recovery was uneventful. Final pathologic studies revealed a moderately differentiated primary small-bowel adenocarcinoma with extension into the muscularis propria, invasion into the dermis with clear margins, and negative nodes with no evidence of dysplasia (Fig 1).

CASE 2.—A 54-year-old man with a history of ulcerative colitis presented to Lahey Clinic Medical Center in early 1987 because of difficulty with adherence of the ileostomy appliance. In 1951 he had experienced bloody diarrhea and was diagnosed as having ulcerative colitis. He did well for 13 years but then had a flare-up of disease and underwent total abdominal colectomy and ileostomy. Pathologic studies revealed chronic ulcerative colitis with backwash ileitis. Interval proctectomy was performed one year later. The final pathologic diagnosis was chronic ulcerative colitis with no evidence of dysplasia.

He did well for 12 years. About one year before the present admission he began to have progressive difficulty with adherence of the appliance. On examination, a bluish, comedolike ridge surrounded the stoma, which essentially was floating free in a 4- to 5-cm ulcer (Fig 2). Biopsy revealed invasive adenocarcinoma. Results of preoperative laboratory studies were normal, including a hematocrit level of 0.35 and a serum carcinoembryonic antigen value of 1 ng/mL.

The patient subsequently underwent an en bloc excision of the ileostomy and anterior abdominal wall and transposition of the stoma to the left side. The abdominal wall defect was repaired with synthetic mesh, and the wound was left open to granulate for subsequent skin grafts. At operation, a synchronous small-bowel cancer was located approximately 15 cm proximal to the ileostomy cancer. Pathologic studies revealed two distinct small-bowel cancers. The ileostomy cancer was a poorly to moderately differentiated adenocarcinoma, and the more proximal cancer was a mucin-producing adenocarcinoma (Fig 3). Dysplasia was not evident. Metastases were found in three of five lymph nodes. Each involved lymph node contained metastatic disease representing

Fig 1.—En bloc specimen of ileostomy with attached ileum and anterior abdominal wall.

Fig 2.—Preoperative photograph demonstrating large comedolike ridge with free-floating stoma.

both primary histologic types. At present, the wound is almost completely healed by secondary intention, and the patient has not required skin grafting.

COMMENT

Since the original description in 1969 by Sigler and Jedd,[3] six more cases of adenocarcinoma arising in an ileostomy have been reported.[4-9] Our two patients bring the total number to nine. The majority of patients had a previous proctocolectomy performed for ulcerative colitis.[3-6,8,9] One case has been reported of a patient with familial polyposis in whom an adenocarcinoma developed in the ileostomy. This patient was believed to have an adenocarcinoma arising in a previous villous adenoma.[7] One patient with an ileostomy cancer is not included herein as this was thought to represent contiguous spread of a rectal cancer after resection of an ileorectal anastomosis and subsequent conversion to a Brooke ileostomy.[10]

Both of our patients had a previous diagnosis of chronic ulcerative colitis. Both also had backwash ileitis, which was confirmed by review of original microsections by one of us (M.L.S.). Furthermore, although the first patient was originally diagnosed as having sigmoid cancer, our review demonstrated high-grade dysplasia and not frank invasive cancer, thereby excluding contiguous spread even though the temporal sequence strongly suggested the impossibility.

Fig 3.—Two distinct small-bowel cancers in same patient. Top, Cancer arising in ileostomy was poorly to moderately differentiated adenocarcinoma (hematoxylin-eosin, ×400). Bottom, More proximal ileal cancer was mucin-producing cancer (hematoxylin-eosin, ×100).

*All patients had wide local excision of the carcinoma.

The rarity of small-bowel cancer is well known.[11] The paucity of case reports attests to the fact that carcinoma arising in an ileostomy is even rarer. Some have speculated, therefore, that the presence of chronic inflammation (backwash ileitis), epithelial regeneration, or dysplasia places patients at an increased risk for malignant transformation of the ileum.[3-6,8,12,13] The majority of previous case reports have described the presence of either antecedent backwash ileitis or dysplasia.[3,4,6,8] In addition, others have described patients with ulcerative colitis in whom ileal cancers developed, which suggests that the ileum itself, if involved with backwash ileitis or dysplasia, may have malignant potential.[12-14] Though we have never seen dysplasia in an ileostomy, both of our patients had backwash ileitis noted at their original colectomy.

The pathogenesis of cancers arising in an ileostomy is largely speculative. Thus, review of additional cases will be necessary before patients at high risk for the development of these cancers can be identified. One cannot discount the fact that, with one exception, all patients had chronic ulcerative colitis as their underlying disease, and all patients had antecedent backwash ileitis or dysplasia. These concomitants of colitis may have placed them at higher risk for the development of ileostomy cancer. If backwash ileitis and dysplasia in the ileal mucosa place patients at a higher risk for the development of small-bowel cancer, routine ileoscopy with biopsy of the mucosa may be necessary for surveillance. At present, however, ileostomy cancers are so rare that the cost of a widespead program of surveillance cannot be justified. Instead, regular yearly inspection of the stoma by an enterostomal therapist or physician may be sufficient.

As in our two patients, all reported instances of carcinoma in an ileostomy occurred many years after the patient's colectomy (Table). Although biopsy established the diagnosis in our two patients, others have pointed out that biopsies are frequently unreliable and often reveal either atypia or inflammation.[9] One must therefore have a high index of suspicion and undertake aggressive biopsy of any unusual or ulcerated-appearing area. Though a normal biopsy finding does not rule out a malignant neoplasm, the presence of atypia or dysplasia warrants further close follow-up and biopsy.

All patients should be treated with wide local excision and transposition of the stoma to the opposite side. As with other malignant bowel neoplasms, survival appears to be related to the stage of the tumor at the time of the original resection. However, the small number of patients and a lack of follow-up in many preclude any conclusions with respect to long-term survival. Greater awareness of this entity as well as routine yearly follow-up and examination of the stoma by a physician or enterostomal therapist may lead to earlier detection of this rare condition.

Appendicitis in Children: Accuracy of the Barium Enema

Cristian Garcia, MD; Nancy S. Rosenfield, MD; Richard I. Markowitz, MD; John H. Seashore, MD; Robert J. Touloukian, MD; Domenic V. Cicchetti, PhD

The barium enema (BE) may be useful in the diagnosis of atypical appendicitis in children. We analyzed our experience with 18 children in whom appendicitis was suspected and BE was performed. All of the children underwent surgical exploration. Nonfilling of the appendix with cecal indentation, extravasation of barium from the appendix, or both, were considered positive signs of an inflamed appendix on BE. Using these criteria, 12 of 14 cases of proved appendicitis were true positive and two were equivocal. Four children were proved not to have appendicitis; one of these patients had a true-negative BE, two had equivocal BEs, and there was one false-positive BE (Schönlein-Henoch purpura). Extravasation of barium into the peritoneal cavity was noted in one patient; this was a rare complication (*AJDC* 1987;141:1309-1312).

SQUIBB

At risk for aminoglycoside toxicity:

The elderly.

AZACTAM—safer than aminoglycosides for elderly patients*

For a variety of reasons, including their often debilitated condition and serious underlying diseases, elderly patients have been reported to be at increased risk for aminoglycoside-associated toxicities.[1] AZACTAM represents a safer alternative for the treatment of gram-negative infections in these patients, an alternative that is free from the risks of nephrotoxicity† and ototoxicity.[2-5]

AZACTAM—the first monobactam—as effective as the aminoglycosides

In addition to its increased margin of safety, AZACTAM offers clinical and microbiological effectiveness equal to aminoglycosides in the treatment of gram-negative infections, such as peritonitis, intraabdominal abscess, and gangrenous appendicitis.[6-8] Its bactericidal activity is well suited for monotherapy when a susceptible gram-negative pathogen has been identified and is an ideal complement to gram-positive or anaerobic agents when empirical therapy is indicated.

**Dosage adjustment, based on estimated creatinine clearance, may be necessary in elderly patients.*
†Demonstrated in animal studies and in human volunteer studies. In clinical trials involving 4,570 subjects, transient elevations in serum creatinine were rarely observed.

For a discussion of INDICATIONS AND USAGE (including susceptible organisms), CONTRAINDICATIONS, WARNINGS, PRECAUTIONS, and ADVERSE REACTIONS, please consult brief summary on the following page.

The logical alternative to aminoglycosides

Azactam® instead.

aztreonam

The logical alternative to aminoglycosides

Azactam® instead.

aztreonam

AZACTAM® FOR INJECTION
Aztreonam For Injection

DESCRIPTION—AZACTAM (aztreonam, Squibb) is the first member of a new class of antibiotics classified as monobactams. AZACTAM is a totally synthetic bactericidal antibiotic with activity against a wide spectrum of gram-negative aerobic pathogens. The monobactams, having a unique monocyclic beta-lactam nucleus, are structurally different from other beta-lactam antibiotics.

AZACTAM For Injection is a sterile, nonpyrogenic, sodium-free, white to yellowish-white lyophilized cake, containing approximately 780 mg arginine per gram of aztreonam for intramuscular or intravenous use following constitution. Aqueous solutions of the product have a pH in the range of 4.5-7.5.

INDICATIONS AND USAGE—Before initiating treatment with AZACTAM, appropriate specimens should be obtained for isolation of the causative organism(s) and for determination of susceptibility to aztreonam. Treatment with AZACTAM may be started empirically before results of the susceptibility testing are available; subsequently, appropriate antibiotic therapy should be continued.

AZACTAM For Injection is indicated for the treatment of the following infections caused by susceptible gram-negative microorganisms: **Urinary Tract Infections** (complicated and uncomplicated), including pyelonephritis and cystitis (initial and recurrent) caused by *Escherichia coli, Klebsiella pneumoniae, Proteus mirabilis, Pseudomonas aeruginosa, Enterobacter cloacae, Klebsiella oxytoca**, *Citrobacter* species* and *Serratia marcescens**. **Lower Respiratory Tract Infections,** including pneumonia and bronchitis caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Haemophilus influenzae, Proteus mirabilis, Enterobacter* species and *Serratia marcescens**. **Septicemia** caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Proteus mirabilis**, *Serratia marcescens** and *Enterobacter* species. **Skin and Skin-Structure Infections,** including those associated with postoperative wounds, ulcers and burns caused by *Escherichia coli, Proteus mirabilis, Serratia marcescens, Enterobacter* species, *Pseudomonas aeruginosa, Klebsiella pneumoniae,* and *Citrobacter* species*. **Intra-abdominal Infections,** including peritonitis caused by *Escherichia coli, Klebsiella* species, including *K. pneumoniae, Enterobacter* species including *E. cloacae**, *Pseudomonas aeruginosa, Citrobacter* species* including *C. freundii** and *Serratia* species* including *S. marcescens**. **Gynecologic Infections,** including endometritis and pelvic cellulitis caused by *Escherichia coli, Klebsiella pneumoniae**, *Enterobacter* species* including *E. cloacae**, and *Proteus mirabilis**.

AZACTAM is indicated for adjunctive therapy to surgery in the management of infections caused by susceptible organisms, including abscesses, infections complicating hollow viscus perforations, cutaneous infections and infections of serous surfaces. AZACTAM is effective against most of the commonly encountered gram-negative aerobic pathogens seen in general surgery.

Concurrent Therapy—Concurrent initial therapy with other antimicrobial agents and AZACTAM is recommended before the causative organism(s) is known in seriously ill patients who are also at risk of having an infection due to gram-positive aerobic pathogens. If anaerobic organisms are also suspected, therapy should be initiated using an antianaerobic agent concurrently with AZACTAM. Certain antibiotics (e.g., cefoxitin, imipenem) may induce high levels of beta-lactamase *in vitro* in some gram-negative aerobes such as *Enterobacter* and *Pseudomonas* species, resulting in antagonism to many beta-lactam antibiotics including aztreonam. These *in vitro* findings suggest that such beta-lactamase inducing antibiotics not be used concurrently with aztreonam. Following identification and susceptibility testing, appropriate antibiotic therapy should be continued.

CONTRAINDICATION—Aztreonam is contraindicated in patients with known allergy to this antibiotic.

WARNINGS—Careful inquiry should be made for a history of hypersensitivity reaction to any antibiotic or other drugs. Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. It is recommended that patients who have had immediate hypersensitivity reactions (e.g., anaphylactic or urticarial) to penicillins and/or cephalosporins should be followed with special care. If an allergic reaction to aztreonam occurs, discontinue the drug and institute supportive treatment as appropriate (e.g., maintenance of ventilation, pressor amines, antihistamines, corticosteroids). Serious hypersensitivity reactions may require epinephrine and other emergency measures.

PRECAUTIONS—General: In patients with impaired hepatic or renal function, appropriate monitoring is recommended during therapy. If an aminoglycoside is used concurrently with aztreonam, especially if high dosages of the former are used or if therapy is prolonged, renal function should be monitored because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. The use of antibiotics may promote the overgrowth of nonsusceptible organisms, including gram-positive organisms and fungi. Should superinfection occur during therapy, appropriate measures should be taken.

Carcinogenesis, Mutagenesis, Impairment of Fertility—Carcinogenicity studies in animals have not been performed. Genetic toxicology studies performed *in vivo* and *in vitro* with aztreonam in several standard laboratory models revealed no evidence of mutagenic potential at the chromosomal or gene level. Two-generation reproduction studies in rats at daily doses up to 20 times the maximum recommended human dose, prior to and during gestation and lactation, revealed no evidence of impaired fertility. There was a slightly reduced survival rate during the lactation period in the offspring of rats that received the highest dosage, but not in offspring of rats that received five times the maximum recommended human dose.

Pregnancy—Pregnancy Category B: Aztreonam crosses the placenta and enters the fetal circulation. Studies in pregnant rats and rabbits, with daily doses up to 15 and 5 times, respectively, the maximum recommended human dose, revealed no evidence of embryo- or fetotoxicity or teratogenicity. No drug induced changes were seen in any of the maternal, fetal or neonatal parameters that were monitored in rats receiving 15 times the maximum recommended human dose of aztreonam during late gestation and lactation. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, aztreonam should be used during pregnancy only if clearly needed.

Nursing Mothers—Aztreonam is excreted in breast milk in concentrations that are less than 1% of concentrations determined in simultaneously obtained maternal serum; consideration should be given to temporary discontinuation of nursing and use of formula feedings.

Pediatric Use—Safety and effectiveness have not been established in infants and children.

ADVERSE REACTIONS—Local reactions such as phlebitis/thrombophlebitis following IV administration, and discomfort/swelling at the injection site following IM administration occurred at rates of approximately 1.9% and 2.4%, respectively. Systemic reactions (considered to be related to therapy or of uncertain etiology) occurring at an incidence of 1 to 1.3% include diarrhea, nausea and/or vomiting, and rash. Reactions occurring at an incidence of less than 1% are listed within each body system in order of decreasing severity: *Hypersensitivity*—anaphylaxis. *Hematologic*—pancytopenia, neutropenia, thrombocytopenia, anemia, leukocytosis, thrombocytosis. *Gastrointestinal*— abdominal cramps; rare cases of *C. difficile*-associated diarrhea or gastrointestinal bleeding have been reported. *Dermatologic*—purpura, erythema multiforme, urticaria, exfoliative dermatitis, petechiae, pruritus, diaphoresis. *Cardiovascular*— hypotension, transient ECG changes (ventricular bigeminy and PVC). *Respiratory*—one patient experienced flushing, chest pain, and dyspnea. *Hepatobiliary*—hepatitis, jaundice. *Nervous System*—seizure, confusion, vertigo, paresthesia, insomnia, dizziness. *Musculoskeletal*—muscular aches. *Special Senses*—tinnitus, diplopia, mouth ulcer, altered taste, numb tongue, sneezing and nasal congestion, halitosis. *Other*—vaginal candidiasis, vaginitis, breast tenderness. *Body as a Whole*—weakness, headache, fever, malaise.

Adverse Laboratory Changes—Those reported without regard to drug relationship during clinical trials were: *Hepatic*—elevations of AST (SGOT), ALT (SGPT), and alkaline phosphatase; signs or symptoms of hepatobiliary dysfunction occurred in less than 1% of recipients (see above). *Hemic*—increases in prothrombin and partial thromboplastin times, eosinophilia, positive Coombs test. *Renal*—increases in serum creatinine.

OVERDOSAGE—If necessary, aztreonam may be cleared from the serum by hemodialysis and/or peritoneal dialysis.

DOSAGE AND ADMINISTRATION—Dosage adjustments are recommended for patients with impaired renal function. In elderly patients, estimates of creatinine clearance should be obtained and appropriate dosage modifications made if necessary.

HOW SUPPLIED—AZACTAM For Injection (Aztreonam For Injection)—Lyophilized—is supplied in single-dose 15 mL vials containing **500 mg,** or **1 g**/vial; in single-dose 30 mL vials containing **2 g**/vial; and in single-dose 100 mL intravenous infusion bottles containing **500 mg** or **1 g** or **2 g**/bottle.

Consult package insert before prescribing AZACTAM (aztreonam).

Brief Clinical Note

Successful Reconstruction of Late Portal Vein Stenosis After Hepatic Transplantation

Velma P. Scantlebury, MD; Albert B. Zajko, MD; Carlos O. Esquivel, MD, PhD; Ignazio R. Marino, MD; Thomas E. Starzl, MD, PhD

• Stenosis of the portal vein anastomosis occurred in three pediatric patients seven to 42 months after transplantation. Dominant symptoms were those of portal hypertension and hypersplenism. Diagnosis was made by angiography. Successful surgical reconstruction was possible in all three patients.

(*Arch Surg* 1989;124:503-505)

Biliary tract complications and thrombosis of the hepatic artery are the most common technical problems observed following orthotopic liver transplantation (OLT).[1,2] In contrast, portal vein (PV) complications are unusual; however, they are associated with high morbidity and mortality.[3-6] Three pediatric patients presented 7, 10, and 42 months after OLT with PV stenoses that were successfully treated by excision of the stenotic segment and reanastomosis.

PATIENTS AND METHODS

The condition of the PV, hepatic artery, and vena cava is determined routinely with ultrasonography in all liver transplant recipients. Between March 1980 and January 1986, three of 184 children who survived more than three months after transplantation had evidence of PV stenosis. The diagnosis was confirmed by selective angiography. In one patient (case 3), venous pressures were measured across the stenosis after transhepatic catheterization of the PV. The following parameters were reviewed: age, indication for transplantation, time interval between OLT and diagnosis of PV stenosis, symptoms, physical and laboratory findings at the time of diagnosis, angiograms, the type of technique for secondary reconstruction, and clinical outcome. The technique for liver transplantation has been previously reported.[7]

RESULTS

The Table summarizes the profile of these three patients and their clinical features at the time PV stenosis was diagnosed. Two of the three patients were symptomatic. The other patient (case 2) had no overt symptoms, although she had mild hepatic dysfunction. On further evaluation, she was found to have splenomegaly and sonographic findings of hepatofugal flow. Because of this, she underwent angiographic evaluation. The cause of hepatic dysfunction was from a stricture of the common bile duct.

Angiographic Findings

All three patients underwent selective celiac and superior mesenteric angiography. In each case, stenosis of the PV anastomosis was identified (Fig 1, left).

Two patients (cases 1 and 3) underwent further evaluation by transhepatic catheterization of the PV to determine if there was a significant pressure gradient across the anastomotic stenosis. Successful catheterization of the PV was possible in both cases. However, in only one patient could the catheter be advanced across the stenosis to measure a gradient (Fig 2). In the other patient, transhepatic portal venography clearly demonstrated a marked stricture even though a gradient could not be measured (Fig 3).

In two patients (cases 1 and 3), evidence of portal hypertension was found as manifested by gastroesophageal varices (Fig 2). In the third patient (case 2), no varices were seen despite the presence of a severe stenosis (Fig 1, left). This last patient underwent follow-up angiography after operative revision of the PV anastomosis, documenting a widely patent PV (Fig 1, right).

Operative Findings

Operation was performed through the same subcostal incision that had been used for the transplantation. In one patient (case 3), the choledochojejunostomy was not taken down because mobilization of the Roux-en-Y allowed adequate exposure of the PV. In the other two cases, the choledochojejunostomy was taken down to facilitate the exposure. Both of these patients (cases 1 and 2) had biliary strictures.

Stenosis of the PV in all three patients was at the anastomoses. The gross pathologic findings were similar in each case. The veins were phlebosclerotic, with focal calcification and foreign-body reaction at the site of the

3/6	Biliary hypoplasia	42	Fatigue	Splenomegaly	Thrombocytopenia and leukopenia

Fig 1.—Case 2. Left, Portal vein anastomotic stenosis (arrow) demonstrated on venous phase of superior mesenteric arteriogram. Poststenotic dilatation of portal vein is evident. Right, Widely patent portal vein anastomosis (arrow) demonstrated on venous phase of superior mesenteric arteriogram performed six days after portal vein revision. Decrease in previously seen poststenotic dilatation is shown.

Fig 2.—Case 3. Portal vein anastomotic stenosis (arrow) demonstrated on transhepatic portogram. Prominent gastric varices are seen. Pressure in splenic vein was 29 mm Hg, and pressure in intrahepatic portal vein was 12 mm Hg.

anastomoses. In one patient (case 1), a recent clot was found in the donor side of the PV that extended into the hilum. Histologic examination of this specimen showed mural thrombosis with recanalization. Thrombectomy was performed.

In each case the anastomosis was excised by removing a ring of vein measuring 1 to 2 cm long after obtaining proximal and distal vascular control. In all three cases the length of the vein was adequate for allowing reapproximation of the two ends without tension. The anastomoses were performed end-to-end with 7-0 polypropylene suture. Systemic heparinization was not used. All patients recovered successfully and were discharged in excellent condition. The spleen in all three patients was noted to have decreased in size at the time of last follow-up.

COMMENT

Portal vein thrombosis after OLT occurs more frequently in pediatric patients. Symptoms of portal hypertension are the primary manifestations. Lerut et al[3] reported seven cases of PV thrombosis following OLT, with an overall incidence of 1.8%. Five of the seven patients developed variceal hemorrhage.

Previous portosystemic shunt and partial or complete thrombosis of the portal system requiring thrombectomy

Fig 3.—Case 1. Marked stenosis of portal vein anastomosis demonstrated on transhepatic portogram (arrow). Catheter could not be advanced across stenosis to measure pressure gradient.

at the time of transplantation are thought to be contributing factors to the development of postoperative PV complications. However, not all patients demonstrate an obvious cause. Of the seven cases reported by Lerut, only three had contributing factors. One patient had a portacaval shunt, one had a thrombosed PV, and one had hypoplasia of the PV. None of the three patients described herein had any contributing cause for the development of PV stenosis following transplantation. However, dense scarring in the portal area may have contributed; two of the three recipients also had a stricture at the site of bile duct anastomosis. The best possibility is that technical errors were made at the time of the original transplantation. The fact that secondary repair was possible without vein grafts might suggest that the cuffs were originally made too long, which consequently caused kinking or distortion.

In all three cases, the diagnosis was suspected by physical examination and confirmed by angiography. Evidence of a recent clot in the portal vein extending into the hilum of the liver was found in one patient (case 1). This clot was not demonstrated by angiographic studies performed three and eight days before revision and may have been contributed to by the instrumentation. Pathologic findings of focal calcification, thickening, and fibrosis in the area of the anastomotic suture line were common to all cases.

The status of the extrahepatic PV should be evaluated in patients after transplantation with recurring symptoms of portal hypertension, hypersplenism, or both. Ultrasonography can be performed for screening, but definitive diagnosis requires angiography. Successful surgical correction of PV anastomotic stenosis can be achieved with little morbidity. The possibility of balloon dilatation of the strictures after transhepatic PV catheterization was not seriously considered for these patients, but this may be a viable nonoperative option for the future.

This study was supported in part by research grants from the Veterans Administration, Pittsburgh, and grant AM 29961 from the National Institutes of Health, Bethesda, Md.

ARCHIVES OF INTERNAL MEDICINE

Frequency of Isolated Proximal Colonic Polyps Among Patients Referred for Colonoscopy

David A. Lieberman, MD, Frederic W. Smith, MD

The American Cancer Society now advocates screening asymptomatic populations over the age of 40 to 50 years for colonic malignancy. It is possible, however, that fecal occult blood testing and sigmoidoscopy to 60 cm would fail to identify patients with adenomatous polyps located only in the proximal colon. The purpose of this study was to determine how many patients without polyps in the distal 60 cm of the colon would have more proximal lesions. Ninety-eight consecutive patients with positive fecal blood test results or suspicious barium enema results were studied, using the assumption that if they had been seen six months earlier, when asymptomatic, they would have been candidates for screening examination. Forty-one (42%) of 98 patients had adenomatous polyps or cancer, and 15 (37%) of these patients had isolated proximal lesions. The polyp detection rate from 0 to 60 cm was significantly less than the detection rate for a full colonoscopy (27% vs 42%). We conclude that isolated proximal colonic polyps may be common (*Arch Intern Med* 1988;148:473-475).

Cardiac Contusion

The Effect on Operative Management of the Patient With Trauma Injuries

Patrick Ross, Jr, MD, PhD; Linda Degutis, MSN; Christopher C. Baker, MD

• Sixty-four patients with cardiac contusion documented by electrocardiographic changes and creatine kinase MB fraction assay following blunt chest injury were reviewed to assess the impact of cardiac contusion on subsequent management. Fifty-eight patients had elevated creatine kinase MB levels; 35 patients had electrocardiographic abnormalities, including ST-segment and T-wave changes (25), premature ventricular contraction (ten), right bundle-branch block (nine), atrioventricular block (three), atrial fibrillation (three), and premature atrial contraction (two). Thirty patients underwent general anesthesia. There were only four perioperative complications: ventricular ectopy, ventricular fibrillation, nodal rhythm, and pulmonary edema. There were no deaths attributable to cardiac contusion. In summary, patients with blunt trauma who have sustained a cardiac contusion can undergo elective operation with a low incidence of complication. In the emergency setting, however, hemodynamic monitoring for early detection of arrhythmias is indicated.

(*Arch Surg* 1989;124:506-507)

Cardiac injury as a consequence of blunt chest trauma is being recognized with increasing frequency. Cardiac contusion represents a major category within the spectrum of cardiac injuries, with an estimated 17% to 20% of patients sustaining blunt chest trauma.[1-3] Since cardiac contusion was first described,[4,5] efforts have been directed toward delineating criteria that allow precise documentation of this injury.[6-14] Specifics of management have been limited to patients developing complications. Thus, patients with cardiac contusion have been treated with protocols developed for patients with recent myocardial ischemia. Several clinical reports and animal experiments have documented significant cardiac dysfunction following blunt injury, including arrhythmias and ventricular dysfunction.[7,9,15,16]

Since cardiac morbidity may be severe, cardiac contusion could be expected to influence the course of the multiply injured patient. Therefore, this study was initiated to address the impact of the presence of cardiac contusion on the management of the patient with multiple trauma, with specific reference to subsequent operative management for other injuries.

PATIENTS AND METHODS

The records of 100 patients admitted to Yale–New Haven (Conn) Hospital between January 1984 and July 1985 with the diagnosis of cardiac contusion were reviewed. Data were extracted on initial presentation, hospital course, operations, and medical history. Cardiac contusion was diagnosed either by electrocardiogram (ECG) or creatine kinase MB fraction (CK-MB) assay based on results obtained during the first 72 hours of hospitalization. The ECG criteria included arrhythmias, atrial or ventricular ectopy, conduction defects, and ischemic changes. Elevation of the CK-MB percentage over 2.5% constituted a positive test.

Accepted for publication May 5, 1988.

RESULTS

Patient Characteristics

Sixty-four patients sustained cardiac contusion by the criteria outlined above. Forty-five were male patients and 19 were female patients. The age distribution ranged from 7 to 89 years. The mean age was 37 years. The majority of the patients were injured in motor vehicle or motorcycle accidents (85%), with the remainder sustaining injury as pedestrians (6%) and from falls or industrial accidents (9%).

Associated Injuries

Forty patients (63%) had additional chest injuries and 18% of the patients were hypotensive (systolic pressure, 90 mm Hg) at the scene or on arrival in the emergency room. Concomitant chest injuries included rib fractures (n = 25), pneumothorax and hemothorax (n = 12), pulmonary contusion (n = 11), sternal fracture (n = 5), clavicle fracture (n = 3), and aortic tear (n = 1). The mean number of organ systems injuries exclusive of the chest was two.

Diagnostic Method

Fifty-eight patients (91% of the study population) had elevated levels of the CK-MB fraction: 29 patients (45%) had CK-MB elevation alone and 29 patients had elevated CK-MB levels and ECG abnormalities (Table). The mean CK-MB rise was 0.04, with a range from 0.03 to 0.12. The peak serum CK-MB level occurred at admission in 21 patients and at eight hours after injury in an additional 29 patients. Fifty-seven of 58 patients with elevated levels of CK-MB fractions exhibited a maximal CK-MB level by 16 hours after admission.

Thirty-five patients (55%) manifested ECG abnormalities; six of these 35 patients had ECG changes without an accompanying CK-MB release. Electrocardiographic abnormalities were as follows: ST-segment alteration (n = 12), T-wave changes (n = 13), premature ventricular contractions (n = 10), right bundle-branch block (n = 9), atrioventricular block (n = 3), atrial fibrillation (n = 3), and premature atrial contraction (n = 2).

Operative Complications

Thirty patients underwent general anesthesia for exploratory laparotomy, repair of complex lacerations, or open reduction and internal fixation of fractures. Only four of these patients had perioperative complications, and there

Total	**58** (90.6)	**6** (9.4)	**64 (100)**

*ECG indicates electrocardiogram; CK-MB, creatine kinase MB isoenzyme.

were no deaths attributable to cardiac contusion. The complications included ventricular ectopy, ventricular fibrillation, nodal rhythm, and pulmonary edema; each event occurred in a single patient. The complications appeared to be unrelated to older age, a history of cardiac disease, level of CK-MB, or total number of systems injured.

COMMENT

Cardiac contusion is a frequent and significant sequela of blunt chest trauma, and efforts should be made to document this lesion when it is suspected. Historical features, including symptoms and mechanism of injury, suggest the diagnosis, which can be confirmed by serial ECGs and measurement of specific cardiac enzyme levels. Additionally, recent reports suggest that two-dimensional echocardiography and radionuclide angiography may be sensitive indicators of myocardial injury.[12,14] Both tests assess ventricular function; abnormalities in ventricular wall motion may correlate with injury. These reports, however, did not address the impact of the injury on the patient's hospital course. In the current study, two-dimensional echocardiography and radionuclide angiography were not used primarily because the tests were cumbersome to perform in the patient with multiple injuries. The role of either modality in the diagnosis of cardiac contusion will require further evaluation.

Previous studies have documented right and left ventricular dysfunction, persistent arrhythmias, and malignant arrhythmias in both clinical reports and experimental models.[9,17-9] These earlier data suggested that patients who had sustained cardiac contusion were at high risk for perioperative cardiac complications. The results reported here, however, demonstrate that patients with injuries with cardiac contusion can be operated on with a low risk (13%) of complications. The complications were easily managed and significantly there was no associated mortality. It is important to note that preoperative evaluation does not allow detection of the population at risk for development of these complications, since complications were not associated with patient age, extent of other injuries, or history of cardiac disease. Thus, all patients with this diagnosis should have perioperative cardiac monitoring.

The findings in this study carry substantial clinical relevance. Frequently, the patient with multiple trauma injuries undergoes delayed operation (particularly for fractures or reconstruction) because of fear of complications associated with cardiac contusion. Conversely, it has become increasingly clear[20] that early definitive fixation of fractures is critical to achieving an optimal outcome in the multiply injured patients. The findings in this study show that patients with cardiac contusion may undergo surgery with a surprisingly low risk of complications.

We conclude several points from this study on cardiac contusion. First, cardiac contusion is a common problem in the patient with trauma injuries, but ECG manifestations of injury may be absent initially in up to 45% of patients. Second, hemodynamic monitoring is indicated in patients requiring emergency operation for trauma injuries in whom cardiac contusion is suspected. Third, preparations for early detection and treatment of arrhythmias must be made in patients undergoing semielective surgery, since preoperative factors do not identify patients at risk. Finally, multiply injured patients who have sustained a cardiac contusion can undergo elective operation with a low incidence of complications.

Invited Editorial Comment

The article by Ross and colleagues again points out that cardiac contusion is a common problem in the population with blunt trauma and that these patients may undergo operation with an expected low rate of cardiac complications.

It remains difficult to know just how often cardiac contusion occurs. All studies (even prospective analyses) are hampered by the lack of an accepted "gold standard" against which to measure any diagnostic test (eg, CK-MB level and ECG). The more sophisticated the test (echocardiogram, multiple-gated acquisition [MUGA] scan), the more frequently the diagnosis of cardiac contusion is made.

The investigators have relied on elevated CK-MB isoenzyme levels and abnormal ECG to define cardiac contusion. It is certainly possible that they are underestimating the true incidence. It is well documented that cardiac contusion can exist at surgery or autopsy with no preoperative or antemortem ECG evidence. Similarly, it has been demonstrated that myocardial biopsy specimens from ventricles of young victims may contain almost no MB isoenzyme content.

Although all would agree with Ross and coworkers that preparations for early detection and treatment of arrhythmias is necessary, some would disagree with their point that preoperative factors do not identify patients at risk. One group has documented an incidence of dysrhythmia that is 13 times greater when two-dimensional echocardiographic findings are abnormal. In most institutions, however, it remains difficult to obtain such studies at odd hours; therefore, one must be prepared to treat arrhythmias in every patient with blunt chest trauma.

Most important, it is pointed out by Ross et al that patients who have sustained "cardiac contusion" can undergo operation safely. One should not forego the substantial benefits of early fixation of skeletal fractures because of concern for dysrhythmia or pump failure.

Endorectal Ileal Pullthrough

To the Editor.—The article by Fonkalsrud et al[1] in the September 1988 issue of the ARCHIVES[1] presents the progression of technical improvements in endorectal ileal pullthrough with better end results. The operation can still present problems. The terminal ileum has specific absorptive capability and mechanism to slow the intestinal stream.[2] It would be interesting to have noted how much of the terminal ileum is retained. The distal ileal 4 cm is a zone of elevated pressure. Its resting pressure is 20 mm Hg greater than colonic pressure.[3] It does not permit reflux, even with distal obstruction to the point of cecal rupture. Bacterial colonization proximal to the junction is rare. This may be an important factor in preventing reflux enteritis, especially in an ileal reservoir.

The ileal mucosa extends to 1 cm of the apex of the protuberance, and a transitional mucosa extends to the apex.[4] Retention of the ileocecal junction musculature may eliminate or modify the need of an ileal reservoir. Professor David Johnston (Department of Surgery, Leeds University, England, oral communication, Oct 5, 1988) has so far done ten such procedures with good initial results in eight of them. It will be interesting to follow up his progress. This may be an initial effort in a new direction.

LAWRENCE BRASLOW, MD
Riverside, Calif

1. Fonkalsrud EW, Stelzner M, McDonald N: Experience with the endorectal ileal pullthrough with lateral reservoir for ulcerative colitis and polyposis. *Arch Surg* 1988;123:1053-1058.
2. Braslow L: Ileocecal valve: Misconceptions. *Arch Surg* 1982;117:249.
3. Davenport HW: *Physiology of the Digestive Tract*, ed 5. Chicago, Year Book Medical Publishers Inc, 1982, p 80.
4. Braslow L: Ileocecostomy. *Arch Surg* 1988;123:782.

In Reply.—We appreciate Dr Braslow's suggestions and recommendations regarding the endorectal ileal pullthrough procedure. As indicated in our article, the ileum is divided approximately 1 to 2 cm from the ileocecal valve unless there is active disease in the terminal ileum, in which case a small amount of ileum is resected. After mobilizing the superior mesenteric artery up to its origin from the aorta, the terminal ileum is divided approximately 15 cm from the end, but preserving the blood supply to the distal segment. The reservoir is constructed in a side-to-side manner over a distance of approximately 12 to 13 cm, which leaves an ileal "spout" distal to the lower end of the reservoir of approximately 1.5 to 2 cm.

With regard to preserving the ileocecal valve and a portion of ileum for the pullthrough segment, it has been our experience that almost all patients with ulcerative colitis will have involvement of the entire colon, including the cecum. In most patients, however, the cecum is the least involved segment, although it is quite likely to develop a flare-up if it is preserved after the colon and rectum are removed. In addition, the blood supply to the cecum is largely dependent on the ileocolic artery, which is not sufficiently long to permit the cecum to extend to the anus. We question the feasibility of placing the cecum in the rectal canal for anastomosis to the anus, considering the high likelihood of recurrent colitis and the tenuous blood supply. Nonetheless, we are very interested in Dr Braslow's clinical experience and look forward to hearing more about his results over the course of time.

Lastly, we are unclear about the term *reflux enteritis* in an ileal reservoir after a pullthrough procedure. Reservoir inflammation or pouchitis is almost invariably related to fecal stasis in the ileal pouch. This is often due to rectal stricture or a long ileal spout.

Hepatic Packing in Major Hepatic Trauma

To the Editor.—I read with great interest the recent article of Stain et al[1] in the October 1988 issue of the ARCHIVES. Although I certainly agree with their major conclusion, ie, that hemorrhage is the major cause of mortality in patients with severe liver injury, I must take issue with their relative condemnation of hepatic packing with planned reexploration for obtaining hemostasis in such patients. I submit a report of a recent case that supports the practice of hepatic packing in major hepatic trauma, including juxtahepatic venous injury.

Report of a Case.—A 17-year-old healthy male patient was involved in a motor vehicle accident May 18, 1988. He was admitted while in shock to a community hospital in rural Georgia. After a brief attempt at resuscitation he underwent celiotomy and was found to have exsanguinating hemorrhage from the liver. Due to the limited resources in this small hospital, no attempt was made to repair this injury, and the liver was packed and the abdomen closed. He was transferred by helicopter to Crawford Long Hospital of Emory University, Atlanta, Ga, a distance of 160 km, having received 6 U of packed red blood cells during surgery and transport.

On arrival at Crawford Long Hospital he was in hemodynamically stable condition. He was admitted to the intensive care unit and underwent transfusion with fresh-frozen plasma to correct coagulopathy. Complete evaluation at that time revealed a fracture of the right humerus and right iliac wing but no other injuries. There was no evidence of ongoing hemorrhage.

After a 36-hour period of stabilization, the site was reexplored on May 20, 1988, at which time he was found to have a massive stellate laceration of the right lobe of the liver, a tear of the right hepatic vein, and a tear of the retrohepatic vena cava, which had decompressed through the liver laceration. The right hepatic vein was ligated and the retrohepatic vena caval injury repaired using an atriocaval shunt. During this operative procedure there was significant blood loss and subsequent hypothermia, resulting in coagulopathy. Thus, no attempt was made at débridement of devitalized liver. The abdomen was again packed and he was returned to the intensive care unit for stabilization and correction of coagulopathy and hypothermia. The site was reexplored on May 23, 1988, and devitalized liver tissue was débrided. After this final procedure he required ventilator support for 5 days due to adult respiratory distress syndrome and required percutaneous computed tomographic scan–directed drainage of a right subphrenic abscess on the 14th postoperative day. Otherwise, his postoperative course was unremarkable.

Comment.—I feel that this case illustrates the value of hepatic packing in providing temporary hemostasis. During this period of temporary hemostasis, coagulopathy and hypothermia can be reversed and resources amassed to care for these devastating injuries. As noted above, packing can control even major juxtahepatic venous injuries, allowing temporary hemostasis. Hepatic packing clearly has a place in the management of liver injuries, as already noted.[2]

CHARLES M. FERGUSON, MD, FACS
Atlanta, Ga

1. Stain SC, Yellin AE, Donovan AJ. Hepatic trauma. *Arch Surg.* 1988;123:1251-1255.
2. Feliciano DV, Mattox KL, Jordan GL. Intra-abdominal packing for control of hepatic hemorrhage: a reappraisal. *J Trauma.* 1981;21:285-290.

In Reply.—Dr Ferguson's well-documented case demonstrates the value of packing a major hepatic and juxtahepatic venous injury in two clinical situations. The first indication was as a temporary expedient to permit transfer of the patient to a site more suitable for definitive treatment. We cited Blumgart and colleagues' report[1] in this regard; this clearly is a useful expedient. The second was to permit correction of hypothermia that develops intraoperatively with concurrent coagulopathy. Both Feliciano and associates[2] and Cogbill and associates[3] have reported favorable results with packing of the hepatic wound after repair of major venous injury with ensuing coagulopathy. The survival rates of their patients were 34% and 59%, respectively. We have recently had a favorable experience in a similar circumstance.

Both Feliciano et al[2] and Cogbill et al[3] and their respective associates also reported that packing was ineffective when undertaken as a desperation measure for continuing hemorrhage. This would be consistent with the experience that we reported. Perhaps the decision to pack should be made earlier in the course of the operation. Our report was not intended to condemn packing. The five patients that we treated with packing all died because of continuing hemorrhage. We stated, "This should not be interpreted as a condemnation of the technique and may reflect patient selection."

Additional reports that precisely document the nature of the hepatic injuries treated with packing will be important. Such reports, though relatively rare in the recent literature, should provide guidance for the selection of patients most likely to benefit from packing and for evaluation of results. This evaluation should include documentation regarding the value of packing in controlling hemorrhage from major exposed and unrepaired juxtahepatic venous and hepatic vein injuries.

Intestinal Malrotation and Midgut Volvulus With Intussusception: An Unusual Association

To the Editor.—Intestinal malrotation with midgut volvulus is an important surgical emergency in pediatric practice. Successful outcome of this clinical condition depends on prompt diagnosis and timely surgical intervention. Delay in diagnosis can lead to an increase in mortality and morbidity. Malrotation volvulus is associated with other anomalies of the gastrointestinal tract in 15% to 31% of cases,[1-3] but its association with intussusception is very rare. Two such cases of malrotation volvulus associated with intussusception are reported herein, and the literature is reviewed briefly.

Report of Cases.—CASE 1.—An 8-month-old girl presented with a two-day history of bloody diarrhea, irritability, and green vomiting. Examination of the abdomen disclosed a mobile tender mass in the left iliac fossa with exaggerated bowel sounds but no distention. A rectal examination disclosed bright red blood. A plain abdominal roentgenogram demonstrated a dilated stomach and duodenal loop with a paucity of gas distally.

At surgery, an ileocolic intussusception was found and was reduced manually. After reduction of the intussusception it was seen that proximal gut loops were collapsed and twisted clockwise. The duodenojejunal junction was found to be on the right of the midline and a well-defined band of Ladd was seen. The small gut was derotated, a Ladd's procedure was performed, and an appendectomy was done. The postoperative period was uneventful.

Diagram showing simultaneous ileocolic intussusception, volvulus of midgut, and band of Ladd.

CASE 2.—A 1½-year-old boy presented with a seven-day history of green vomiting and a four-day history of blood passed through the rectum. Examination showed the patient to be moderately dehydrated. Examination of the abdomen disclosed a mobile tender mass in the left iliac fossa with exaggerated bowel sounds, without any distention. During a rectal examination the apex of an intussusception was felt. A plain roentgenogram of the abdomen disclosed a dilated stomach with no gas distally. At laparotomy an ileocolic intussusception reaching up to the rectum along with the band of Ladd and volvulus of the midgut were seen (Figure). Reduction of the intussusception, untwisting of the volvulus, Ladd's procedure, and an appendectomy were performed. The postoperative period was uneventful.

Comment.—Sporadic cases of intestinal malrotation associated with intussusception have been cited from time to time in many series.[1-4] Brereton et al[5] described malrotation of the gut in 40% of cases of intussusception, but the incidence of malrotation and midgut volvulus with intussusception is extremely rare; to my knowledge, only one case has been reported (by Ornstein et al[6]). Association of malrotation volvulus with intussusception can complicate management by causing gangrene of the gut if the volvulus goes unrecognized. Patients with intussusception with associated malrotation of the gut may present a confusing picture on hydrostatic reduction.[3] An absence of abdominal distention and a paucity of gas distally on an abdominal roentgenogram are two possible indicators that may point toward associated intestinal malrotation and midgut volvulus in a case of intussusception. If such an association is suspected, the case should be treated surgically instead of with hydrostatic reduction to avoid serious complications such as vascular compromise of the gut due to associated volvulus.

Fine-Needle Aspiration for Breast Masses

To the Editor.—If fine-needle aspiration is to make an economic impact on medical care, it must do so by eliminating surgery for benign lesions. This has been accomplished in the management of thyroid lesions, as documented in numerous studies.[1-3]

In the recent report from Seattle, Wash, published in the January 1988 issue of the ARCHIVES, this point was not made for breast fine-needle aspiration.[4] In fact, there were errors in the calculations presented in Table 2 of that report. If one defines "positive" as any result requiring biopsy and "negative" as indicating conservative close follow-up only, then the calculations are as appear in the accompanying Table.

Despite these adjustments, the persistent flaw of the study lies in the five fine-needle aspiration negative results that were biopsy positive. Other studies have shown better results.[5-7] One wonders whether increased proficiency with the technique of fine-needle aspiration could have reduced these. For this reason, many authorities have recommended that the pathologist collect the specimen, smear it, read it, and interpret it.[8] Only then will the goals of high specificity and, thereby, high negative predictive value be achieved, so as to impact maximally on the medical care system.

HOWARD GOLDMAN, MD
Martinez, Calif

Decision Analysis Values		
Value	**Definition (No. of Cases)**	**%**
Sensitivity	True positives (93) / True positives (93) + false negatives (5)	95
Specificity	True negatives (23) / True negatives (23) + false positives (19)	55
Positive predictive value	True positives (93) / True positives (93) + false positives (19)	83
Negative predictive value	True negatives (23) / True negatives (23) + false negatives (28)	82

	Biopsy Positive	Biopsy Negative
FNA Positive	TP: 70 + 19 + 4	FP: 7 + 12
FNA Negative	FN: 5	TN: 23

FNA indicates fine-needle aspiration; TP, true positive; FP, false positive; FN, false negative; and TN true negative.

Books

Color Atlas of Head and Neck Surgery: Face, Skull and Neck, by Jatin Shah, 256 pp, with illus, $149.50, Orlando, Fla, Grune & Stratton Inc, 1987.

Head and neck surgery has become an increasingly complex field. Since it incorporates techniques in such fields as neurosurgery, maxillofacial surgery, oral surgery, and microvascular surgery, the practicing head and neck surgical oncologist needs to refine existing technical skills and constantly learn new ones. This volume, designed for the aspiring head and neck surgeon, attempts to fill that information gap; unfortunately, it only partly succeeds.

The volume is a photographic atlas of head and neck surgical procedures categorized by anatomic regions. It begins with some perfunctory chapters on operating room setup, anesthetic considerations, and basic surgical techniques.

The remaining chapters show intraoperative photographs of commonly performed operations, supplemented by a clearly written text. For the most part, the photographs, taken by the author, nicely document the procedure and take the reader through a clear description of how he does it. Where the anatomy or the procedure is particularly complex, simple line drawings are used to assist the reader. Unfortunately, none of the photographs is labeled, and several of the images would have been improved by one larger F stop or a closer, faster lens. For experienced surgeons, these deficiencies are not major. For the novice, however, it would be difficult to use this book as a guide to the cervicofacial landscape. I found the chapters on neck dissection and skull-base surgery to be particularly informative.

At a time when we have high-quality videotape, videodisc, and computer imaging, the surgical atlas still has a place. It is a convenient, readily accessible reference and does not require sophisticated viewing equipment. However, learning to perform an operation from still pictures is like understanding a movie by looking at the still shots on a marquee. Only by watching the flow of the action and the interrelationship of the anatomic characters in three dimensions can you appreciate the content and complexity of the surgery.

Despite its drawbacks, I would recommend this book for reference libraries and for the libraries of experienced surgeons. As the author acknowledges, the single-author approach has its advantages and disadvantages. Fortunately, for the reader, this atlas gives us the advantage of the many things Dr Shah has to teach us.

Limb Salvage and Amputation for Vascular Disease, R. M. Gleenhalgh, C. W. Jamieson, and A. N. Nicolaides, 459 pp, $125, Philadelphia, WB Saunders Co, 1988.

Amputation is the profession's equivalent to Chapter 11 for vascular surgeons; an admission of failure and occasionally the result of poor judgment. This book, edited by three distinguished British vascular surgeons, is an in-depth study of such disease progression and management failure.

Eighty authors from ten countries provide chapters on subjects ranging from the epidemiology of disease and anticipated clinical course following amputation to the need to use a multidisciplinary team in the management of amputee rehabilitation. It is interesting to note that despite the obvious enthusiasm for the team approach, no hard numbers are provided to prove its advantages. Obviously, it is logical to use all the help one can get from such ancillary services, but future studies should try to quantitate the advantages.

I suspect that this book in no way resembles what Professor McColl's Blue Ribbon Governmental Committee had in mind when it asked Gleenhalgh to review artificial limb and rehabilitation centers in the United Kingdom. This aside, the committee received full credit in the resulting publication. It contains a solid and supportive 92-page section involving the rehabilitation team and a compact 189-page critique of diagnostic and operating techniques valuable in managing patients with advanced arteriosclerosis and threatened with limb loss. Those who perform vascular surgery will of course benefit from this part of the book. The clinical setting results in many situations where the slightest mistake in judgment or flaw in technique may mean the difference between limb salvage and amputation.

The book addresses the classic problem of deciding what level of amputation should be performed or whether revascularization is worth a try. As has been the case so often in the past, the critical reader emerges from the discussions with admiration for the scientific ingenuity of the investigators, but also with a vague sense that such new techniques as magnetic resonance imaging, pedal arch arteriography, and transcutaneous oxygen measurement will probably be of no more value than have many other promising techniques that were touted during the past 20 years.

Faced with impending amputation, the vascular surgeon understandably grasps at even the most flexible straws. Mountaineers call such unimpressive support "vegetable belays." This book provides appropriate critical reviews of such adjunct topics as antiplatelet drugs, lumbar sympathectomy, and various forms of chemical vasodilators. If the vascular surgeon chooses to use these techniques, he should at least know the database of their performance.

It is interesting that only the last five pages of *Limb Salvage and Amputation for Vascular Disease* address the comparative cost-effectiveness of amputation and revascularization. This is a subject that primarily interests those who pay for health care. I believe that we surgeons are going to be forced to alter our focus on simple limb survival or graft patency and consider whether patients are more satisfied with repeated hospitalizations and operations or the alternative of amputation. Such redirection of our postrevascularization accounting system, I suspect, will bear out the advantages of attempts to save a limb. We should preempt the obvious criticism with additional reports analyzing the question.

Numerous texts have appeared during the past ten years pertaining to many aspects of peripheral vascular surgery. This is one of the better ones, concentrating as it does on vascular reconstruction and amputation.

Count on

CEFOTAN® IM/IV (cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri*, and *Morganella morganii*).
Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.
Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis,* Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.
Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis,* Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).
Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).
Bone and joint infections caused by *Staphylococcus aureus*.†
***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.
† Efficacy for this organism in this organ system was studied in fewer than ten infections.
PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be

developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21).

Rocephin® ROCHE® IV·IM

ceftriaxone sodium/Roche

Before prescribing, please consult complete product information, a summary of which follows:

INDICATIONS AND USAGE: Rocephin is indicated for the treatment of the following infections when caused by susceptible organisms.

LOWER RESPIRATORY TRACT INFECTIONS caused by *Strep. pneumoniae, Streptococcus* species (excluding enterococci), *Staph. aureus, H. influenzae, H. parainfluenzae, Klebsiella* species (including *K. pneumoniae*), *E. coli, E. aerogenes, Proteus mirabilis* and *Serratia marcescens*.

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus, Staph. epidermidis, Streptococcus* species (excluding enterococci), *E. cloacae, Klebsiella* species (including *K. pneumoniae*), *Proteus mirabilis* and *Pseudomonas aeruginosa*.

URINARY TRACT INFECTIONS (complicated and uncomplicated) caused by *E. coli, Proteus mirabilis, Proteus vulgaris, M. morganii* and *Klebsiella* species (including *K. pneumoniae*).

UNCOMPLICATED GONORRHEA (cervical/urethral and rectal) caused by *Neisseria gonorrhoeae*, including both penicillinase and nonpenicillinase producing strains.

PELVIC INFLAMMATORY DISEASE caused by *N. gonorrhoeae*.

BACTERIAL SEPTICEMIA caused by *Staph. aureus, Strep. pneumoniae, E. coli, H. influenzae* and *K. pneumoniae*.

BONE AND JOINT INFECTIONS caused by *Staph. aureus, Strep. pneumoniae, Streptococcus* species (excluding enterococci), *E. coli, P. mirabilis, K. pneumoniae* and *Enterobacter* species.

INTRA-ABDOMINAL INFECTIONS caused by *E. coli* and *K. pneumoniae*.

MENINGITIS caused by *H. influenzae, N. meningitidis* and *Strep. pneumoniae*. Ceftriaxone has also been used successfully in a limited number of cases of meningitis and shunt infections caused by *Staph. epidermidis* and *E. coli*.

SURGICAL PROPHYLAXIS: Preoperative administration of a single 1 gm dose may reduce incidence of postoperative infections in patients undergoing surgical procedures classified as contaminated or potentially contaminated (*e.g.*, vaginal or abdominal hysterectomy) and in those for whom infection at the operative site presents serious risk (*e.g.*, during coronary artery bypass surgery).

Although ceftriaxone has been shown to have been as effective as cefazolin in the prevention of infection following coronary artery bypass surgery, no placebo-controlled trials have been conducted to evaluate any cephalosporin antibiotic in the prevention of infection following coronary artery bypass surgery. When administered before indicated surgical procedures, a single 1 gm dose provides protection from most infections due to susceptible organisms for duration of procedure.

SUSCEPTIBILITY TESTING: Before instituting treatment with Rocephin, appropriate specimens should be obtained for isolation of the causative organism and for determination of its susceptibility to the drug. Therapy may be instituted prior to obtaining results of susceptibility testing.

CONTRAINDICATIONS: Rocephin is contraindicated in patients with known allergy to the cephalosporin class of antibiotics.

WARNINGS: BEFORE THERAPY WITH ROCEPHIN IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE WHETHER THE PATIENT HAS HAD PREVIOUS HYPERSENSITIVITY REACTIONS TO CEPHALOSPORINS, PENICILLINS OR OTHER DRUGS. THIS PRODUCT SHOULD BE GIVEN CAUTIOUSLY TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE THE USE OF SUBCUTANEOUS EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind to the toxin *in vitro*.

Mild cases of colitis respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte and protein supplementation as indicated.

When the colitis is not relieved by drug discontinuance or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C. difficile*. Other causes of colitis should also be considered.

Rarely, shadows suggesting sludge have been detected by sonograms of the gallbladder in asymptomatic and symptomatic patients. This appears to be reversible on discontinuation of therapy. In a few symptomatic patients receiving higher than usual doses, who underwent surgery, sludge containing traces of ceftriaxone was recovered from surgical specimens. Discontinue therapy in patients who develop signs or symptoms suggestive of gallbladder disease; consider conservative management.

PRECAUTIONS: *GENERAL*: Although transient elevations of BUN and serum creatinine have been observed, at the recommended dosages, the nephrotoxic potential of Rocephin is similar to that of other cephalosporins.

Ceftriaxone is excreted via both biliary and renal excretion (see Clinical Pharmacology). Therefore, patients with renal failure normally require no adjustment in dosage when usual doses of Rocephin are administered, but concentrations of drug in the serum should be monitored periodically. If evidence of accumulation exists, dosage should be decreased accordingly.

Dosage adjustments should not be necessary in patients with hepatic dysfunction; however, in patients with both hepatic dysfunction and significant renal disease, Rocephin dosage should not exceed 2 gm daily without close monitoring of serum concentrations.

Alterations in prothrombin times have occurred rarely in patients treated with Rocephin. Patients with impaired vitamin K synthesis or low vitamin K stores (*e.g.*, chronic hepatic disease and malnutrition) may require monitoring of prothrombin time during Rocephin treatment. Vitamin K administration (10 mg weekly) may be necessary if the prothrombin time is prolonged before or during therapy.

Prolonged use of Rocephin may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection occurs during therapy, appropriate measures should be taken.

Rocephin should be prescribed with caution in individuals with a history of gastrointestinal disease, especially colitis.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Carcinogenesis: Considering the maximum duration of treatment and the class of the compound, carcinogenicity studies with ceftriaxone in animals have not been performed. The maximum

ROCEPHIN® (ceftriaxone sodium/Roche)

duration of animal toxicity studies was six months.

Mutagenesis: Genetic toxicology tests included the Ames test, a micronucleus test and a test for chromosomal aberrations in human lymphocytes cultured *in vitro* with ceftriaxone. Ceftriaxone showed no potential for mutagenic activity in these studies.

Impairment of Fertility: Ceftriaxone produced no impairment of fertility when given intravenously to rats at daily doses up to 586 mg/kg/day, approximately 20 times the recommended clinical dose of 2 gm/day.

PREGNANCY: Teratogenic Effects: Pregnancy Category B. Reproductive studies have been performed in mice and rats at doses up to 20 times the usual human dose and have no evidence of embryotoxicity, fetotoxicity or teratogenicity. In primates, no embryotoxicity or teratogenicity was demonstrated at a dose approximately three times the human dose.

There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nonteratogenic Effects: In rats, in the Segment I (fertility and general reproduction) and Segment III (perinatal and postnatal) studies with intravenously administered ceftriaxone, no adverse effects were noted on various reproductive parameters during gestation and lactation, including postnatal growth, functional behavior and reproductive ability of the offspring, at doses of 586 mg/kg/day or less.

NURSING MOTHERS: Low concentrations of ceftriaxone are excreted in human milk. Caution should be exercised when Rocephin is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness of Rocephin in neonates, infants and children have been established for the dosages described in the Dosage and Administration section. *In vitro* studies have shown ceftriaxone, like some other cephalosporins, can displace bilirubin from serum albumin. Exercise caution before administration to hyperbilirubinemic neonates, especially prematures.

ADVERSE REACTIONS: Rocephin is generally well tolerated. In clinical trials, the following adverse reactions, which were considered to be related to Rocephin therapy or of uncertain etiology, were observed:

LOCAL REACTIONS—pain, induration or tenderness at the site of injection (1%). Less frequently reported (less than 1%) was phlebitis after I.V. administration.

HYPERSENSITIVITY—rash (1.7%). Less frequently reported (less than 1%) were pruritus, fever or chills.

HEMATOLOGIC—eosinophilia (6%), thrombocytosis (5.1%) and leukopenia (2.1%). Less frequently reported (less than 1%) were anemia, neutropenia, lymphopenia, thrombocytopenia and prolongation of the prothrombin time.

GASTROINTESTINAL—diarrhea (2.7%). Less frequently reported (less than 1%) were nausea or vomiting, and dysgeusia.

HEPATIC—elevations of SGOT (3.1%) or SGPT (3.3%). Less frequently reported (less than 1%) were elevations of alkaline phosphatase and bilirubin.

RENAL—elevations of the BUN (1.2%). Less frequently reported (less than 1%) were elevations of creatinine and the presence of casts in the urine.

CENTRAL NERVOUS SYSTEM—headache or dizziness were reported occasionally (less than 1%).

GENITOURINARY—moniliasis or vaginitis were reported occasionally (less than 1%).

MISCELLANEOUS—diaphoresis and flushing were reported occasionally (less than 1%).

Other rarely observed adverse reactions (less than 0.1%) include leukocytosis, lymphocytosis, monocytosis, basophilia, a decrease in the prothrombin time, jaundice, gallbladder sludge, glycosuria, hematuria, anaphylaxis, bronchospasm, serum sickness, abdominal pain, colitis, flatulence, dyspepsia, palpitations and epistaxis.

DOSAGE AND ADMINISTRATION: Rocephin may be administered intravenously or intramuscularly. The usual adult daily dose is 1 to 2 gm given once a day (or in equally divided doses twice a day) depending on the type and severity of the infection. The total daily dose should not exceed 4 grams.

For the treatment of serious miscellaneous infections in children, other than meningitis, the recommended total daily dose is 50 to 75 mg/kg (not to exceed 2 grams), given in divided doses every 12 hours.

Generally, Rocephin therapy should be continued for at least two days after the signs and symptoms of infection have disappeared. The usual duration is 4 to 14 days; in complicated infections longer therapy may be required.

In the treatment of meningitis, a daily dose of 100 mg/kg (not to exceed 4 grams), given in divided doses every 12 hours, should be administered with or without a loading dose of 75 mg/kg.

For the treatment of uncomplicated gonococcal infections, a single intramuscular dose of 250 mg is recommended.

For preoperative use (surgical prophylaxis), a single dose of 1 gm administered 1/2 to 2 hours before surgery is recommended.

When treating infections caused by *Streptococcus pyogenes*, therapy should be continued for at least ten days.

No dosage adjustment is necessary for patients with impairment of renal or hepatic function; however, blood levels should be monitored in patients with severe renal impairment (*e.g.*, dialysis patients) and in patients with both renal and hepatic dysfunctions.

HOW SUPPLIED: Rocephin (ceftriaxone sodium/Roche) is supplied as a sterile crystalline powder in glass vials and piggyback bottles. The following packages are available:

Vials containing 250 mg, 500 mg, 1 gm or 2 gm equivalent of ceftriaxone, piggyback bottles containing 1 gm or 2 gm equivalent of ceftriaxone, bulk pharmacy containers containing 10 gm equivalent of ceftriaxone (NOT FOR DIRECT ADMINISTRATION).

Also supplied as a sterile crystalline powder as follows:

ADD-Vantage Vials** containing 1 gm or 2 gm equivalent of ceftriaxone.

Also supplied premixed as a frozen iso-osmotic, sterile, nonpyrogenic solution of ceftriaxone sodium in 50 mL single dose plastic containers,† as follows:

1 gm equivalent of ceftriaxone, iso-osmotic with approximately 1.9 gm dextrose hydrous, USP added.

2 gm equivalent of ceftriaxone, iso-osmotic with approximately 1.2 gm dextrose hydrous, USP added.

NOTE: Rocephin in the frozen state should not be stored above -20°C.

For manageable hemostasis

Helistat®

ABSORBABLE COLLAGEN HEMOSTATIC SPONGE

On the cutting

Because it's easy to use

Manageable—as in pliable, soft, and malleable, either wet or dry. Helistat® is easily wrapped or packed to conform closely to the surfaces of the bleeding site. Even suture it in place.

Or place the pure collagen, sponge-textured pad directly on multiple bleeding sites. It removes easily—intact—without shedding, fragmenting, or causing rebleeding.

STAT performance

Collagen triggers platelet aggregation,[1] effectively controlling capillary and diffuse bleeding.

And because of its unique Micromesh™ Collagen Matrix, Helistat quickly precipitates the platelet cascade, forming stable, dense clots. Topical application effectively controls bleeding, usually within two to five minutes.

Safe and economical

Tensile strength is maintained when wet, so it's easily and safely manipulated and positioned. Again, the Micromesh matrix tightly binds the collagen fibers, so there's minimal dispersal in the operative site.[2]

Helistat collagen purity minimizes immunoreactive response. In sensitivity evaluations, no agglutination was observed.[2] In situ, Helistat is designed to be totally absorbable.[2]

Conveniently packaged in *three* unit-of-use sizes—1″ x 2″, 3″ x 4″, and 9″ x 10″—Helistat offers *cutting edge technology* proven in hundreds of fully documented clinical cases.

To order Helistat, contact your local drug wholesaler.

For more information about Helistat—and other products *on the cutting edge* of advanced technology developed for efficient wound management—call

1-800-3-MARION, ext. 3105

Helistat®

ABSORBABLE COLLAGEN HEMOSTATIC SPONGE

DESCRIPTION

HELISTAT® Absorbable Collagen Hemostatic Sponge is a soft, white, pliable, nonfriable absorbent sponge. Because of its nonfriable coherent sponge structure, the application of HELISTAT® hemostatic sponge to the site where hemostasis is desired is easily controlled. Unwanted dispersal over the operative site is not encountered.

The basic material from which the HELISTAT® hemostatic sponge is fabricated is collagen obtained from the bovine deep flexor (Achilles) tendon. The tendon is considered to be one of the purest sources for collagen that can be readily obtained and processed in commercial amounts. HELISTAT® hemostatic sponge, being derived from this tendon, is expected to be a very consistent material.

Because of the initial purity of the collagen source and the further purification effected through several purification steps during the processing of the HELISTAT® hemostatic sponge, uniform behavior from this topical hemostat from one application to the next is to be expected.

INDICATIONS

HELISTAT® hemostatic sponge is indicated in surgical procedures (other than in neurological, ophthalmological, and urological surgery) as an adjunct to hemostasis when control of bleeding by ligature or conventional procedures is inefficient or impractical.

INFORMATION FOR USE

On contact with blood, collagen is known to cause aggregation of platelets. Platelets deposit in large numbers on the collagen structure, degranulate, and release coagulation factors that, together with plasma factors, enable the formation of fibrin. The spongy structure of HELISTAT® hemostatic sponge provides for the additional strengthening of the clot.

Topical application of HELISTAT® hemostatic sponge controls bleeding usually within two to five minutes when applied directly to the bleeding site. It can be applied directly to the bleeding site and should not be inadvertently dispersed over areas of the open body cavity. Long-term effects of leaving HELISTAT® hemostatic sponge in situ are presently unknown.

HELISTAT® hemostatic sponge is designed to be totally absorbable if left in situ after hemostasis. If desired, recovery of the sponge after hemostasis is easily accomplished. Implant studies in animals have demonstrated HELISTAT® hemostatic sponge to be absorbed with tissue reaction similar to that observed with other absorbable hemostatic agents.

HELISTAT® hemostatic sponge absorption was evaluated after subcutaneous and intrahepatic implantation in rats. In one out of five animals, complete subcutaneous absorption was observed by day 14, and by day 56, three out of four animals had complete absorption. Complete intraperitoneal absorption was not observed by day 56. As shown with other hemostatic agents, the implantation of HELISTAT® hemostatic sponge also elicits a similar foreign body reaction.

HELISTAT® hemostatic sponge had been evaluated in vitro for the enhancement of bacterial growth of *Staphylococcus aureus* and *Escherichia coli*. The test showed that bacterial growth of *Staphylococcus aureus* and *Escherichia coli* was not enhanced by HELISTAT® hemostatic sponge.

In vivo studies using guinea pigs showed that the incidence of infection (abscess) of incision sites inoculated with *Staphylococcus aureus* was not enhanced by the presence of HELISTAT® hemostatic sponge when compared to another collagen hemostatic agent. However, extent of wound infection tended to be greater than the control with both HELISTAT® hemostatic sponge and another collagen hemostatic agent tested. This tendency is observed with many foreign substances.

HELISTAT® hemostatic sponge was evaluated for potential allergenic sensitivity. A guinea pig maximization study showed that the HELISTAT® hemostatic sponge did not produce irritation or contact sensitization. A chemical assay of HELISTAT® hemostatic sponge compared to one other collagen hemostat showed significantly less specific glycoprotein immunoreactive substances in HELISTAT® hemostatic sponge. A hemagglutination study was conducted evaluating the HELISTAT® hemostatic sponge as the antigen. There was no agglutination observed with HELISTAT® hemostatic sponge.

PRECAUTIONS

As with other hemostatic agents, it is not recommended that the HELISTAT® hemostatic sponge be left in an infected or contaminated space. Safety of this product has not been established in pregnant women.

The HELISTAT® hemostatic sponge is not intended to be used in treating systemic coagulation disorders.

Long-term effects of leaving HELISTAT® hemostatic sponge in situ presently are unknown.

ADMINISTRATION

The HELISTAT® hemostatic sponge should be applied directly to the bleeding surface with pressure applied. The period of time necessary to apply pressure will vary with the type and amount of bleeding to be controlled. In general, one to five minutes should be sufficient. It has been shown that hemostasis usually occurs within two to five minutes. The amount of sponge necessary to achieve hemostasis will depend on the nature and amount of bleeding to be controlled. The HELISTAT® hemostatic sponge may be left in situ whenever necessary. However, the surgeon should remove any excess of the HELISTAT® hemostatic sponge prior to wound closure.

ADVERSE REACTIONS

Adverse reactions reported with a microfibrillar collagen hemostatic agent that were possibly related to its use were adhesion formation, allergic reaction, foreign body reaction, and subgaleal seroma (report of a single case). The use of microfibrillar collagen in dental extraction sockets has been reported to increase the incidence of alveolalgia.

Microfibrillar collagen has also been reported to cause interference with the healing of skin edges when used in the closure of skin incisions and to reduce the strength of methyl methacrylate adhesive when used to attach prosthetic devices to bone surfaces.

Since the HELISTAT® hemostatic sponge is a collagen-based product, adverse reactions experienced with the microfibrillar collagen hemostat may be related.

HOW SUPPLIED

Sterile HELISTAT® Absorbable Collagen Hemostatic Sponge is supplied in the following sizes:

Product Number	Size	Quantity
1174-198001	1 in x 2 in (2.5 cm x 5.0 cm) 2 sq in (12.5 sq cm)	10/box
1174-198002	3 in x 4 in (7.5 cm x 10.0 cm) 12 sq in (75 sq cm)	10/box
1174-198003	9 in x 10 in (23 cm x 25 cm) 90 sq in (575 sq cm)	5/box

Issued 12/88

Available exclusively from and manufactured for:

WOUND CARE DIVISION
MARION LABORATORIES, INC.
KANSAS CITY, MO 64137

Manufactured by Colla-Tec, Inc., a subsidiary of Marion Laboratories, Inc.

ORIGINAL ARTICLES

Preliminary Clinical Experience With the Titanium Greenfield Vena Caval Filter 657
Lazar J. Greenfield, MD, Kyung J. Cho, MD, Ann Arbor, Mich; S. Osher Pais, MD, Baltimore, Md; Michael Van Aman, MD, Columbus, Ohio
• A titanium model of the Greenfield filter provides ease of insertion, and the sheath technique should prevent misplacement.

Arterial Mycotic Aneurysm and Rupture: A Potentially Fatal Complication of Pancreas Transplantation in Diabetes Mellitus 660
Andreas G. Tzakis, MD; Patricia B. Carroll, MD; Robert D. Gordon, MD; Itsuo Yokoyama, MD; Leonard Makowka, MD, PhD; Thomas E. Starzl, MD, PhD, Pittsburgh, Pa
• A mycotic aneurysm must be suspected in patients with a pancreatic transplant who present with unexplained hypotension, cardiac arrest, or gastrointestinal bleeding.

Results of Operative Treatment of Gastrointestinal Tract Tumors in Patients Over 80 Years of Age 662
Ph. Morel, MD; R. A. Egeli, MD; S. Wachtl, MD; A. Rohner, MD, Geneva, Switzerland
• Operative treatment of gastrointestinal tract malignancy in patients greater than 80 years of age improved their activity level and resulted in a 48% survival rate at 3 years.

Surgical Manipulation and the Tensile Strength of Polypropylene Sutures 665
Philip B. Dobrin, MD, PhD, Maywood, Ill
• Accidental knots and grasping with forceps decreased the tensile strength of these sutures.

Thromboxane A_2-Receptor Blockade and Prostacyclin in Porcine *Escherichia coli* Shock 669
Erik Svartholm, MD, PhD; David Bergqvist, MD; Ulla Hedner, MD, PhD; June Ljungberg; Ulf Haglund, MD, PhD, Malmö, Sweden
• Although thromboxane A_2 is one of the mediators of pulmonary vascular responses, it is not important for the hemostatic changes in this model.

Inflammatory Aneurysms of the Abdominal Aorta 673
Hans H. Moosa, MD; Andrew B. Peitzman, MD; David L. Steed, MD; Thomas B. Julian, MD; Fredric Jarrett, MD; Marshall W. Webster, MD, Pittsburgh, Pa
• A CT scan with contrast for periaortic inflammation is the most reliable diagnostic test.

Strategy in Reoperative Surgery for Hyperparathyroidism 676
Polly S. Y. Cheung, MBBS, FRCS; Anders Borgstrom, MD; Norman W. Thompson, MD, Ann Arbor, Mich
• Second operations for hyperparathyroidism will be less frequent after thorough initial neck exploration, correct interpretation of the pathology, and adequate parathyroid resection.

How Accurate Is Fine-Needle Biopsy in Malignant Neoplasia of the Pancreas? 681
Livingston Parsons, Jr, MD, Charles H. Palmer, MD, Albuquerque, NM
• Aspiration biopsy of the pancreas performed percutaneously or intraoperatively was associated with a high incidence of false-negative results.

Colorectal Neodymium-YAG Photoablative Therapy: Comparing Applications and Complications on Both Sides of the Peritoneal Reflection 684
Donald E. Low, MD; Richard A. Kozarek, MD; Terrence J. Ball, MD; David J. Patterson, MD; Lucius D. Hill, MD, Seattle, Wash
• Laser photoablative therapy for colorectal carcinoma can be used with equal efficiency and safety on either side of the peritoneal reflection.

Small-Bowel Perforation Complicating the Open Treatment of Generalized Peritonitis 689
Walter J. B. Mastboom, MD; Han H. C. Kuypers, MD, PhD; Frans J. Schoots, MD; Theo Wobbes, MD, PhD, Nijmegen, the Netherlands
• Small-bowel perforations developed without apparent cause in a number of patients being treated for peritonitis by the open method.

Angiotropin Treatment Prevents Flap Necrosis and Enhances Dermal Regeneration in Rabbits 693
Michael Höckel, MD, PhD, Mainz, West Germany, John F. Burke, MD, Boston, Mass
• Angiotropin pretreatment can prevent flap necrosis and augment dermal regeneration after rounding.

The **ARCHIVES OF SURGERY** (ISSN 0004-0010) is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago, IL 60610, and at additional mailing office.

SUBSCRIPTION RATES—The subscription rates for the ARCHIVES OF SURGERY are as follows: $50 for one year, $85 for two years in the United States and US possessions; all other countries, one year, $60; two years, $105 for surface delivery. (For expedited air delivery to most countries, add $15 surcharge for one year subscription, $30 for two years.) Rates for subscriptions for delivery to Japan or South Korea are available through exclusive agents—contact the publisher. ***Special rates for residents and medical students in the United States and US Possessions are available.*** Address inquiries to the American Medical Association, Circulation and Fulfillment Division, 535 N Dearborn St, Chicago, IL 60610. Phone: (312)280-7168.

CHANGE OF ADDRESS—POSTMASTER, send all address changes to the ARCHIVES OF SURGERY, Attention: Subscription Department, 535 N Dearborn St, Chicago, IL 60610. Notification of address change must be made at least six weeks in advance, include both old and new addresses, a recent mailing label, and your new zip code.

Advertising Principles: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request. The appearance of advertising in AMA publications is not an AMA guarantee or endorsement of the product or the claims made for the product by the manufacturer.

CONTENTS—Continued

Simple Intestinal Obstruction Causes Bacterial Translocation in Man 699
Edwin A. Deitch, MD, Shreveport, La
• Bacteria were cultured from mesenteric lymph nodes obtained from patients with simple intestinal obstruction.

Management of Severe Incisional Abscesses Following Laparotomy: Early Reclosure Under Cover of Metronidazole and Ampicillin 702
Finn Gottrup, MD, PhD, Randers, Denmark; P. Gjøde, MD, Aalborg, Denmark; F. Lundhus, MD, Randers, Denmark; H. Andrup, MD, Aalborg, Denmark; C. N. Holm, MD, Viborg, Denmark; S. Terpling, MD, Randers, Denmark
• Management of abdominal wound abscesses by incision and drainage, antibiotics, and early reclosure was safe and effective.

Oral Prophylaxis With Neomycin and Erythromycin in Colorectal Surgery: More Proof for Efficacy Than Failure 705
Per-Arne Kling, MD, Sven Dahlgren, MD, Umeå, Sweden
• Results were similar with oral neomycin-erythromycin or intravenous cephtriaxone-etronidazole preparation in colorectal surgery.

The Effect of New Monofilament Absorbable Sutures on the Healing of Musculoaponeurotic Incisions, Gastrotomies, and Colonic Anastomoses 708
Pamela A. Foresman; Richard F. Edlich, MD, PhD; George T. Rodeheaver, PhD, Charlottesville, Va
• Two new monofilament absorbable sutures, Maxon and PDS, were equally effective in experimental wounds.

Diagnosis and Treatment of Duodenoenteric Fistulas Complicating Crohn's Disease 712
Kenneth K. W. Lee, MD; Wolfgang H. Schraut, MD, Chicago, Ill
• In patients with Crohn's disease, duodenoenteric fistulas were due to enterocolonic rather than duodenal Crohn's disease.

Excision of the Burn Wound in Patients With Large Burns 718
William F. McManus, MD; Arthur D. Mason, Jr, MD; Basil A. Pruitt, Jr, MD, Fort Sam Houston, Tex
• The apparent advantages of excision of large burn wounds may only reflect patient selection.

Diagnostic Pneumoperitoneum in the Pediatric Patient With a Unilateral Inguinal Hernia 721
Gregory A. Timberlake, MD; M. Gage Ochsner, MD; Randall W. Powell, MD, San Diego, Calif
• In pediatric patients, intraoperative pneumoperitoneum during inguinal herniorrhaphy was used to diagnose a contralateral hernia.

Prostaglandin E_2 in Pyloric Stenosis 724
Gideon Goldman, MD; Elsa Tiomny, MD; Perry J. Kahn, MD; Dalia Somjen, PhD; Zamir Halpern, MD; Tuvia Gilat, MD; Theodor Wiznitzer, MD, Tel-Aviv, Israel
• Decreased PGE_2 levels were present in patients with pyloric obstruction.

The Effect of Endotoxin on Glucose Metabolism in Skeletal Muscle Requires the Presence of Plasma 727
Joseph F. Amaral, MD; Jeffry D. Shearer, MA; Balduino Mastrofrancesco, MS; Donald S. Gann, MD; Michael D. Caldwell, MD, PhD, Providence, RI
• Endotoxin does not have a direct effect on glucose uptake of skeletal muscle.

Hypertonic Saline Resuscitation in a Porcine Model of Severe Hemorrhagic Shock 733
Gregory G. Stanford, MD; C. Richard Patterson, MD; Lynda Payne, RN; Timothy C. Fabian, MD, Memphis, Tenn
• Hypertonic saline was effective in resuscitating pigs with hemorrhagic shock.

CLINICAL NOTES

Percutaneous Nephrostomy in the Management of Renal Candidiasis 739
Orlando Ortiz, MD, Won J. Lee, MD, New Hyde Park, NY
• Percutaneous nephrostomy allowed drainage, extraction of the fungus ball, and irrigation with amphotericin B.

Echinococcal Disease in an Extended Family and Review of the Literature 741
CPT Franco Musio, MC, USA, Dimitrios Linos, MD, Athens, Greece
• Echinococcal disease developed in seven of 11 members of an extended family group.

BRIEF CLINICAL NOTES

Emergent Endoscopic Retrograde Cholangiopancreatography: A Highly Specific Test for Acute Pancreatic Trauma 745
Sharon R. Hayward, MD; Charles E. Lucas, MD; Choichi Sugawa, MD; Anna M. Ledgerwood, MD, Detroit, Mich
• A normal pancreatogram ruled out pancreatic transection in this trauma patient.

Percutaneous Transhepatic Ultrasonic Cholelithotripsy 747
Anurag K. Das, MD; John L. Weinerth, MD; Steven C. Rose, MD; R. Randal Bollinger, MD, PhD, Durham, NC
• Transhepatic lithotripsy was utilized to remove gallstones in this patient.

THE WRONG STUFF?

For patients with no gut function, TPN is the right choice. But feeding only parenterally can cause gut atrophy and lead to physiologic compromise.[1]

It has been estimated 80% to 85% of the patients traditionally placed on TPN can be managed by enteral methods alone.[2]

THE RIGHT STUFF

Because VIVONEX T.E.N. uses the gut, it protects the mucosal barrier and avoids intestinal atrophy that can lead to complications.[1] VIVONEX T.E.N. is clinically comparable to TPN,[3] plus it is the only leading enteral formula that contains the amino acid glutamine. And TPN doesn't contain glutamine, which animal studies have shown to be a key fuel for the small intestine[4] and to maintain the integrity of the intestinal villi and mucosal wall.[5,6]

BECAUSE IT KEEPS
THE GUT WORKING

ETHICON assures quality silk suture production from cocoon to package, to meet your standards for handling and performance.

In fact, all of our suture products undergo this type of scrutiny, including our full line of natural and synthetic sutures. We begin our work with only the finest raw materials available. And the vigilance continues through each stage of the manufacturing process. Whether it's degumming, braiding, dyeing, or needle attachment, every process is inspected every step of the way. Over 200 quality assurance professionals and technicians at ETHICON work to ensure that our standards meet yours.

GENERAL SURGEON

Surgical group serving a small, rural community of approximately 25,000 is looking for a Board Certified or Board Eligible General Surgeon. Surgical staff now consists of 4 general surgeons, one of whom is anticipating retirement. Practice is located next door to a progressive 76-bed acute care hospital. Area is year-round outdoor resort with hunting, fishing, hiking, snow-skiing, water-skiing, and many other outdoor recreational activities. Located 120 miles southeast of Pittsburgh and 200 miles west of Baltimore. West Va. University Medical Center is located 60 miles to the west. Contact: C. William Fedde, M.D., Garrett Surgical Group, Suite 1, 311 N. 4th St., Oakland, Maryland 21550 (301) 334-8282.

GENERAL SURGEON

Board Certified or eligible with a special interest in trauma and critical care to join *200+* physician multi-specialty group. Large referral practice in Big 10 university town. Excellent guarantee with incentive package, liberal fringe benefits and early partnership. Contact:

Robert C. Parker, M.D.
Carle Clinic
Urbana, IL 61801
217-337-3223

GENERAL SURGEON SAN FRANCISCO BAY AREA

Outstanding opportunity for BE/BC general surgeon starting July, 1989. Interesting surgical practice in a beautiful area to live and work. Excellent salary and exceptional benefits, with opportunity to become shareholder in two years and senior partner in three years. Direct inquiries to:

Chief, Department of Surgery
Kaiser Permanente Medical Center
1150 Veterans Blvd.
Redwood City, CA 94063
EEO/AA

METROPOLITAN WASHINGTON, D.C.

Board Certified or Eligible Thoracic, Vascular, Plastic, Neuro and General Surgeons wanted to join a multi-specialty group practice. Group serving 250,000 members of Kaiser Permanente of the Mid-Atlantic States Region. Busy surgical practice. Excellent salary and benefit package. Send CV with all inquiries to:

William J. McAveney, M.D.
Physician Recruitment Director
Capital Area Permanente Medical Group, P.C.
4200 Wisconsin Avenue, N.W.
Suite 300

"H

on't have to think of you,
you're the best."

Surgeon focus.

Where it is can make a big difference in the procedure.

For decades, surgeons have helped us design and develop our contributions to the surgical suite.

Our goals have always been the same — reliable support without distraction. Today, our experience is helping you move better and stand easier during most procedures — letting you concentrate on why you're really there... right from the start.

AMSCO
Right from the start

DEFINING A NEW STANDA

D* FOR EMPIRIC THERAPY

For Infection Following
Complicated Abdominal Surgery

BETTER THAN AMINOGLYCOSIDE COMBINATIONS FOR MOST PATIENTS

For These Reasons...

- ☐ Gram-negative coverage of an aminoglycoside plus
- ☐ Gram-positive coverage of cefazolin plus
- ☐ Anaerobic coverage of clindamycin or metronidazole plus
- ☐ Enterococcal coverage of ampicillin plus
- ☐ Tolerability profile characteristic of beta-lactam antibiotics

...PRIMAXIN Is a Better Choice for Empiric Therapy

Coverage of specified agents is based upon the Microbiology Section of the Prescribing Information as published in the 1988 *Physicians' Desk Reference*®

Data available from Merck Sharp & Dohme, West Point, PA 19486.

PRIMAXIN is contraindicated in patients who have shown hypersensitivity to any component of this product. Before initiating therapy with PRIMAXIN, careful inquiry should be made concerning previous hypersensitivity reactions to penicillins, cephalosporins, other beta-lactams, and other allergens. If an allergic reaction to PRIMAXIN occurs, discontinue the drug. Serious hypersensitivity reactions may require epinephrine and other emergency measures.

In vitro activity does not necessarily imply *in vivo* effectiveness.

*when indicated organisms are suspected at indicated sites

INTRAVENOUS

PRIMAXIN®

(Imipenem-Cilastatin Sodium/MSD)

Please see Brief Summary of Prescribing Information on following page.

Copyright © 1988 by Merck & Co., Inc.

DEFINING A NEW STANDARD FOR EMPIRIC THERAPY

INTRAVENOUS

PRIMAXIN®

(Imipenem-Cilastatin Sodium/MSD)

Contraindications: PRIMAXIN is contraindicated in patients who have shown hypersensitivity to any component of this product.

Warnings: SERIOUS AND OCCASIONALLY FATAL HYPERSENSITIVITY (anaphylactic) REACTIONS HAVE BEEN REPORTED IN PATIENTS RECEIVING THERAPY WITH BETA LACTAMS. THESE REACTIONS ARE MORE APT TO OCCUR IN PERSONS WITH A HISTORY OF SENSITIVITY TO MULTIPLE ALLERGENS.

THERE HAVE BEEN REPORTS OF PATIENTS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY WHO HAVE EXPERIENCED SEVERE HYPERSENSITIVITY REACTIONS WHEN TREATED WITH ANOTHER BETA LACTAM. BEFORE INITIATING THERAPY WITH 'PRIMAXIN,' CAREFUL INQUIRY SHOULD BE MADE CONCERNING PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, OTHER BETA LACTAMS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION TO 'PRIMAXIN' OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis has been reported with virtually all antibiotics, including PRIMAXIN; therefore it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use. This colitis may range in severity from mild to life threatening.

Mild cases of pseudomembranous colitis may respond to drug discontinuance alone. In more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte, and protein supplementation, and the use of a drug such as oral vancomycin, as indicated. Isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—CNS adverse experiences such as confusional states, myoclonic activity, and seizures have been reported during treatment with PRIMAXIN, especially when recommended dosages were exceeded. These experiences have occurred most commonly in patients with CNS disorders (e.g., brain lesions or history of seizures) and/or compromised renal function. However, there have been reports of CNS adverse experiences in patients who had no recognized or documented underlying CNS disorder or compromised renal function.

Patients with severe or marked impairment of renal function, whether or not undergoing hemodialysis, had a higher risk of seizure activity when receiving maximum recommended doses than those with no impairment of renal function; therefore, maximum recommended doses should be used only where clearly indicated (see DOSAGE AND ADMINISTRATION).

Patients with creatinine clearances of ≤5 mL/min/1.73 m^2 should not receive PRIMAXIN unless hemodialysis is instituted within 48 hours.

For patients on hemodialysis, PRIMAXIN is recommended only when the benefit outweighs the potential risk of seizures.

Close adherence to the recommended dosage and dosage schedules is urged, especially in patients with known factors that predispose to convulsive activity. Anticonvulsant therapy should be continued in patients with known seizure disorders. If focal tremors, myoclonus, or seizures occur, patients should be evaluated neurologically, placed on anticonvulsant therapy if not already instituted, and the dosage of PRIMAXIN re-examined to determine whether it should be decreased or the antibiotic discontinued.

As with other antibiotics, prolonged use of PRIMAXIN may result in overgrowth of nonsusceptible organisms. Repeated evaluation of the patient's condition is essential. If superinfection occurs during therapy, appropriate measures should be taken. While PRIMAXIN possesses the characteristic low toxicity of the beta-lactam group of antibiotics, periodic assessment of organ system function during prolonged therapy is advisable.

Drug Interactions—Since concomitant administration of PRIMAXIN and probenecid results in only minimal increases in plasma levels of imipenem and plasma half-life, it is not recommended that probenecid be given with PRIMAXIN.

PRIMAXIN should not be mixed with or physically added to other antibiotics. However, PRIMAXIN may be administered concomitantly with other antibiotics, such as aminoglycosides.

Carcinogenesis, Mutagenesis, Impairment of Fertility—Gene toxicity studies were performed in a variety of bacterial and mammalian tests *in vivo* and *in vitro*. The tests were: V79 mammalian cell mutation assay (PRIMAXIN alone and imipenem alone), Ames test (cilastatin sodium alone), unscheduled DNA synthesis assay (PRIMAXIN), and *in vivo* mouse cytogenicity test (PRIMAXIN). None of these tests showed any evidence of genetic damage.

Reproduction tests in male and female rats were performed with PRIMAXIN at dosage levels up to 8 times the usual human dose. Slight decreases in live fetal body weight were restricted to the highest dosage level. No other adverse effects were observed on fertility, reproductive performance, fetal viability, growth, or postnatal development of pups. Similarly, no adverse effects on the fetus or on lactation were observed when PRIMAXIN was administered to rats late in gestation.

Pregnancy—Pregnancy Category C: Teratogenicity studies with cilastatin sodium in rabbits and rats at 10 and 33 times the usual human dose, respectively, showed no evidence of adverse effect on the fetus. No evidence of teratogenicity or adverse effect on postnatal growth or behavior was observed in rats given imipenem at dosage levels up to 30 times the usual human dose. Similarly, no evidence of adverse effect on the fetus was observed in teratology studies in rabbits with imipenem at dosage levels at the usual human dose.

Teratology studies with PRIMAXIN at doses up to 11 times the usual human dose in pregnant mice and rats during the period of major organogenesis revealed no evidence of teratogenicity.

Data from preliminary studies suggest an apparent intolerance to PRIMAXIN (including emesis, inappetence, body weight loss, diarrhea, and death) at doses equivalent to the average human dose in pregnant rabbits and cynomolgus monkeys that is not seen in nonpregnant animals in these or other species. In other studies, PRIMAXIN was well tolerated in equivalent or higher doses (up to 11 times the average human dose) in pregnant rats and mice. Further studies are under way to evaluate these findings.

There are, however, no adequate and well-controlled studies in pregnant women. PRIMAXIN should be used only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers—It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when PRIMAXIN is administered to a nursing woman.

Pediatric Use—Safety and effectiveness in infants and children below 12 years of age have not yet been established.

Adverse Reactions: PRIMAXIN is generally well tolerated. Many of the 1,723 patients treated in clinical trials were severely ill and had multiple background diseases and physiological impairments, making it difficult to determine causal relationship of adverse experiences to therapy with PRIMAXIN.

Local Adverse Reactions—Local adverse clinical reactions that were reported as possibly, probably, or definitely related to therapy with PRIMAXIN were: phlebitis/thrombophlebitis (3.1%), pain at the injection site (0.7%), erythema at the injection site (0.4%), vein induration (0.2%), infused vein infection (0.1%).

Systemic Adverse Reactions—The most frequently reported systemic adverse clinical reactions that were reported as possibly, probably, or definitely related to PRIMAXIN were: nausea (2.0%), diarrhea (1.8%), vomiting (1.5%), rash (0.9%), fever (0.5%), hypotension (0.4%), seizures (0.4%) (see PRECAUTIONS), dizziness (0.3%), pruritus (0.3%), urticaria (0.2%), somnolence (0.2%).

Additional adverse systemic clinical reactions reported as possibly, probably, or definitely drug related occurring in less than 0.2% of the patients or reported since the drug was marketed are listed within each body system in order of decreasing severity: *Gastrointestinal*—pseudomembranous colitis (see WARNINGS), hemorrhagic colitis, gastroenteritis, abdominal pain, glossitis, tongue papillar hypertrophy, heartburn, pharyngeal pain, increased salivation; *CNS*—encephalopathy, tremor, confusion, myoclonus, paresthesia, vertigo, headache, psychic disturbances; *Special Senses*—transient hearing loss in patients with impaired hearing, tinnitus; *Respiratory*—chest discomfort, dyspnea, hyperventilation, thoracic spine pain; *Cardiovascular*—palpitations, tachycardia; *Renal*—oliguria/anuria, polyuria; *Skin*—erythema multiforme, facial edema, flushing, cyanosis, hyperhidrosis, skin texture changes, candidiasis, pruritus vulvae; *Body as a Whole*—polyarthralgia, asthenia/weakness.

Adverse Laboratory Changes—Adverse laboratory changes without regard to drug relationship that were reported during clinical trials or reported since the drug was marketed were: *Hepatic*—increased SGPT, SGOT, alkaline phosphatase, bilirubin, and LDH; *Hemic*—increased eosinophils, positive Coombs test, decreased WBC and neutrophils, including agranulocytosis, increased WBC, increased platelets, decreased platelets, decreased hemoglobin and hematocrit, increased monocytes, abnormal prothrombin time, increased lymphocytes, increased basophils; *Electrolytes*—decreased serum sodium, increased potassium, increased chloride; *Renal*—increased BUN, creatinine; *Urinalysis*—presence of urine protein, urine red blood cells, urine white blood cells, urine casts, urine bilirubin, and urine urobilinogen.

NOTE: Due to the high antimicrobial activity of PRIMAXIN, it is recommended that the maximum total daily dosage not exceed 50 mg/kg/day or 4.0 g/day, whichever is lower.

How Supplied: PRIMAXIN is supplied as a sterile powder mixture in vials, infusion bottles, and single-dose ADD-Vantage®† vials containing imipenem anhydrous and cilastatin sodium as follows: 250 mg imipenem equivalent and 250 mg cilastatin equivalent; 500 mg imipenem equivalent and 500 mg cilastatin equivalent.

Caution: The suspension from vials is not for direct infusion.

Preliminary Clinical Experience With the Titanium Greenfield Vena Caval Filter

Lazar J. Greenfield, MD; Kyung J. Cho, MD; S. Osher Pais, MD; Michael Van Aman, MD

• Preliminary clinical experience in 40 patients from three institutions is reported for a new titanium model of the Greenfield vena caval filter. The titanium filter is slightly larger than the standard stainless steel filter and can be loaded into a 12 F diameter carrier system as opposed to the 24 F stainless steel filter. In patients ranging from 17 to 94 years of age, percutaneous insertions were made from the right femoral vein in 24 patients, the left femoral vein in 11 patients, and the right internal jugular in 2 patients. Operative access was obtained in 1 patient each from the right femoral, right jugular, and a lumbar vein at laparotomy. Insertion was completed in all cases but 1 and only 1 patient (3%) showed postoperative femoral vein thrombosis. Distal filter migration was seen in 3 cases (7.5%) without sequelae, and there was no proximal migration. The titanium Greenfield vena caval filter provides improved ease of insertion, and the sheath technique should prevent misplacement. Distal migration should be preventable by techniques to promote hook engagement at the time of insertion.

(*Arch Surg.* 1989;124:657-659)

Mechanical protection against pulmonary thromboembolism often is required instead of or as an adjunct to anticoagulation. Since it was introduced in 1972, the Greenfield inferior vena caval filter has established a record of safety and effectiveness with long-term patency rates in excess of 95% in the experience of several institutions.[1-3] This predictable patency is a feature of the cone-shaped design that allows emboli to be trapped without occlusion of the cava, thereby promoting subsequent spontaneous thrombolysis independent of anticoagulation. The high rate of long-term patency has allowed positioning of the filter above the level of the renal veins when indicated, usually because of thrombus propagation to that level.[4,5]

The original technique for insertion of the filter carrier system was by surgical exposure of the jugular or femoral vein. With further development of the Seldinger technique for percutaneous insertion of catheters and dilators over a guide wire, it has been possible to insert the carrier system percutaneously through a 24 F sheath.[6] However, percutaneous insertion from the femoral route has been associated with a higher incidence of postinsertion femoral vein thrombosis.[7] To reduce the size of the carrier system and to facilitate percutaneous insertions, a titanium alloy model of the Greenfield filter (TGF) has been developed and has been shown to be effective in trapping experimental emboli.[8] In addition, a modification of the technique of insertion has been made using a longer sheath through which the carrier system is passed, and additional safety features have been incorporated into the control handle. This article summarizes our preliminary clinical experience with the modified filter and insertion system.

MATERIALS AND METHODS

The TGF is fabricated from a titanium alloy that has elastic properties allowing it to be compressed into a 12 F carrier. It is slightly longer than the standard stainless steel filter (SGF), with a length of 4.7 cm as opposed to the 4.4 cm length of the SGF (Fig 1). The TGF is also broader at the base (38 mm) than the SGF (30 mm, Fig 1) and lighter in weight at 0.25 g as compared with 0.56 g for the SGF. The mechanical properties of the TGF have been tested extensively, and it shows remarkable resistance to flexion fatigue and induced corrosion.[9] It exerts a force of fixation on the wall of the vena cava that is greater than the SGF at diameters over 22 mm but less than the SGF at diameters less than 22 mm.

The technique for placement uses a guide wire inserted from either the femoral or jugular vein over which a dilator system and attached 14 F sheath can be passed. Once the sheath and dilator are in the inferior vena cava at the level of filter placement, the dilator is withdrawn, and the TGF carrier is then passed under fluoroscopic control to the level of intended insertion. Both the carrier catheter and sheath are withdrawn as a unit to release the filter. After discharge, the carrier and sheath are withdrawn and gentle pressure is applied to the insertion site.

Preliminary clinical experience was obtained in 40 patients from April to October 1988 in the hospitals of the University of Michigan, Ann Arbor (16 patients), the University of Maryland, (8 patients), and Ohio State University, Columbus (16 patients). Their ages ranged from 17 to 94 years, and the sex distribution was 23 female patients and 17 male patients. Percutaneous access for insertion was obtained from the right femoral vein in 24 patients, the left femoral vein in 11 patients, and the right internal jugular vein in 2 patients. Operative access for insertion was utilized in 3 patients, 1 each from the right femoral vein, the right internal jugular vein, and a lumbar vein as part of a resection of a retroperitoneal sarcoma. In the latter case, the lumbar vein was the final connection of the tumor mass and because fluoroscopy was not available, the carrier was palpated in the vena cava for suprarenal discharge.

The indications for filter placement included a contraindication to anticoagulation in 33 patients, a complication of anticoagulation forcing it to be discontinued in 5 patients, failure of anticoagulation to prevent pulmonary embolism in 1 patient, and for prophylaxis in the absence of embolism in 1 patient with severe pulmonary hypertension. Preoperatively, it was planned to position the filter below the renal veins in 35 patients and above the renal veins in 5 patients. Follow-up studies included duplex Doppler and B-mode ultrasound examination, computed tomographic scans, plain roentgenograms, and magnetic resonance imaging in 1 patient.

RESULTS

The percutaneous introducer system generally worked well at each of the institutions, but one us (S.O.P.) found it necessary to use balloon dilation in the tract of three patients. Most cases were managed by progressive dilation over the guidewire to 14 F, after which the carrier was passed through the sheath for filter discharge. Failure to pass the dilators occurred in 1 patient, a 56-year-old woman with terminal adenocarcinoma who had a very tight stricture of the inferior vena cava at the level of the hepatic veins. No further attempts at filter placement were made because her narrowed

Fig 1.—Top, Side view of the stainless steel (left) and titanium (right) models of the Greenfield vena caval filter. Bottom, Axial view of the stainless steel (left) and titanium (right) models of the Greenfield filter. The titanium filter has a broader base (38 mm) than the steel filter (30 mm), allowing it to be placed in larger veins.

Fig 2.—The titanium Greenfield filter is shown as inserted percutaneously in an infrarenal position.

Fig 3.—Three patients were observed to have filter movement with respiration as shown. One of these patients showed a subsequent distal migration of the filter, but the other two remained stable. EXP indicates expiration; INSP, inspiration.

cava was felt to provide some protection against massive thromboembolism. She died 10 days later with no evidence of pulmonary embolism. The remainder of the insertions were uncomplicated, although the angle between the iliac vein and vena cava occasionally required simultaneous advancement of carrier and sheath to enter the vena cava. The TGF was inserted below the renal veins in 35 patients (Fig 2) and above the renal veins in 4, as intended. All of the filters were aligned well within the cava with the exception of one with a tilt of 20°.

There were no complications related to the insertion technique, but at follow-up at 1 week, one patient (3%) showed femoral vein thrombosis at the site of insertion. Filter movement of 4, 5, and 7 mm was noted with respiration in three patients who showed reversible downward displacement with inspiration (Fig 3). One of these patients showed subsequent distal migration of the filter that was also seen in two other patients (7.5%) for distances of 2 to 3 cm. Two of the filters were placed suprarenally in very large vena cavas (30 and 32 mm in diameter) and found subsequently to have slipped with angulation and entry of some of the limbs of the filter in the right renal vein. There was no proximal migration and no evidence of occlusion of any of the filters or recurrent embolism, although the period of follow-up was limited.

There were two deaths that occurred postoperatively in addition to the patient who had an unsuccessful attempt at filter placement. A 46-year-old woman with end-stage carcinoma died of sepsis, and an 82-year-old man with hypertension and bradycardia died 1 day postoperatively. Neither was felt to have sustained recurrent embolism, but autopsies were not obtained. There was one late death in a 31-year-old woman with an inherited disorder of antithrombin III who continued to have recurrent episodes of venous thrombosis despite anticoagulation therapy. Follow-up duplex and magnetic resonance imaging scans showed continued patency of her filter, but she developed subclavian vein thrombosis and progressive pulmonary hypertension. She died 4 months after filter insertion and may have sustained recurrent embolism, al-

Fig 4.—A patient with thrombosis of her jugular and iliac veins had vena caval access only through the Hickman catheter shown on venogram. Balloon dilation of the catheter tract was necessary to allow passage of the 12 F carrier system for filter placement.

though repeated lung scans were unchanged before her death.

COMMENT

Although most patients with deep vein thrombosis or pulmonary embolism can be managed by anticoagulation alone, it is essential to provide timely mechanical protection from thromboembolism for those patients who have a contraindication to anticoagulation, who have a complication of anticoagulation forcing it to be discontinued, who fail anticoagulation and sustain recurrent embolism, who have a propagating tail on a thrombus in a major vein, who have required pulmonary embolectomy, or who sustain recurrent embolism after another device within or ligation of the inferior vena cava. Although most patients have adequate protection from infrarenal filter placement, the predictable high patency rate of the SGF has allowed it to be inserted above the renal veins and in the superior vena cava under special circumstances.[10] Most commonly, however, placement below the level of the renal veins is made using a guidewire that facilitates passage of the carrier system and reduces the likelihood of misplacement.[11]

The present carrier for the SGF is large enough to present mechanical problems occasionally in both introduction into the vein and passage through the eustachian valve at the atriocaval junction. Reducing the diameter of the carrier system from 24 F to 12 F has facilitated both entry and positioning from the jugular or femoral vein and completely eliminated bleeding during percutaneous filter insertion. Only one patient had sufficient stenosis of the vena cava to prohibit passage of the smaller carrier. In another patient, the first one to receive a TGF, the jugular, femoral, and iliac veins were thrombosed and the only access was through a Hickman catheter in the right femoral vein. After balloon dilatation of that tract (Fig 4), it was possible to pass the TGF carrier into position for filter placement.

The higher proportion of patients intended for suprarenal placement of the filter in this series (12.5%) reflects our increasing satisfaction with the performance of the filter at this level. In a review of the long-term experience at the Medical College of Virginia, the 10-year follow-up of suprarenal Greenfield filters showed that all of the filters remained patent in the patients who returned for yearly examination. The distal migration of two TGF suprarenal filters in our study may be due to the larger diameter of the vena cava at that level, and in each patient the cava was larger than the recommended limit for insertion of the SGF.

Although measurements of lateral force show a greater force for the TGF than the SGF at larger diameters, the lack of migration is likely due to lack of penetration of the hooks of the filter into the vena cava wall. This could be addressed by an additional tap on the filter from below at the time of discharge to engage the hooks into the wall of the cava, but further studies will be necessary to determine the optimal method of fixation. Minimal filter movement over time was reported in 27 patients in two series[12,13] and in the experience of one of us (L.J.G.) in 69 patients with measured radiographic follow-up over a period of 9 years.[14] Most importantly, proximal migration has been reported only when the filter was discharged into a markedly dilated vein[15] or when a thrombus formed within the carrier tethering the limbs of the filter and preventing fixation.

The behavior of titanium in the circulation has been studied and it shows neither additional thrombogenicity nor greater tissue reaction compared with stainless steel.[9] Experimental thrombus capture and resolution is similar to the SGF,[8] and its durability should be comparable in view of its increased corrosion resistance and tolerance to flexion stress. The addition of a sheath to the delivery system adds additional protection against premature discharge and misplacement since discharge before the intended location would be into the sheath that could easily be withdrawn.

Arterial Mycotic Aneurysm and Rupture

A Potentially Fatal Complication of Pancreas Transplantation in Diabetes Mellitus

Andreas G. Tzakis, MD; Patricia B. Carroll, MD; Robert D. Gordon, MD;
Itsuo Yokoyama, MD; Leonard Makowka, MD, PhD; Thomas E. Starzl, MD, PhD

• Mycotic aneurysm at the site of a Carrel patch arterial anastomosis occurred in four patients who had undergone whole pancreas transplantation 2.5 to 14.5 months previously. In all patients, the graft had been removed, leaving the Carrel patch on the iliac artery. The aneurysms ruptured into the intestine or the extraperitoneal space. The ruptures were sudden and life-threatening in three of four cases. This diagnosis must be suspected in patients with a history of pancreas transplantation in the immediate or distant past if they present with unexplained hypotension, cardiac arrest, or gastrointestinal tract bleeding.

***(Arch Surg.* 1989;124:660-661)**

Pancreas transplantation has been performed with increasing frequency in patients with diabetes mellitus, often at the same time as renal transplantation.[1-5] Mycotic arterial aneurysms developed in four patients at the site of the Carrel patch, which was used to rearterialize the whole pancreas homograft. This life-threatening complication could be confused with cardiac arrhythmias or myocardial infarction, the most common causes of sudden death in advanced diabetes.

PATIENTS AND METHODS

The four complications occurred in 16 patients who received 17 pancreas grafts between 1983 and 1985 in a pilot study of whole pancreas transplantation at the University of Pittsburgh (Pa).[6] The 4 patients were 24 to 36 years of age and had type I diabetes mellitus and a history of ketosis for 18 years or more. All patients had neuropathy and retinopathy. All but 1 had renal failure, which was treated earlier or at the same time with cadaveric kidney transplantation.

A pancreaticoduodenal graft was used in each case. The donor celiac axis and origin of the superior mesenteric artery were included in a Carrel patch of the donor aorta, which was anastomosed to the side of the recipient common iliac artery.[6,7] The end of the graft portal vein was anastomosed to the side of the common iliac vein of the recipient. The graft exocrine secretions were directed into the recipient jejunum by anastomosing the duodenum directly into the recipient jejunum (cases 1 and 2) or through a defunctionalized Roux-en-Y limb of jejunum (cases 3 and 4), with techniques that have been described elsewhere.[6,7] Immunosuppression was achieved with cyclosporine and prednisone, supplemented with azathioprine and monoclonal antibody (OKT3, Orthoclone), as indicated.

Perioperative antibiotics administered at the time of transplantation consisted of cefazolin in patients 1 and 2, cefotaxime in patient 3, and cefotaxime and ampicillin in patient 4.

RESULTS

Clinical Presentation

Failed pancreatic grafts had been removed 5 days to 14 months before the aneurysm ruptures occurred (Table). In patients 1, 2, and 3, the ruptures occurred, fortunately, while the patients were in the hospital. Patient 1 had a peripancreatic abscess drained 1 week before pancreatectomy. No abscess was encountered in patient 2. There was no disruption of the enteric anastomosis. Both patients became pulseless at the same time that they developed swelling in the area of the graft and bleeding through the graft pancreatectomy incision. The incisions were opened at the bedside, and the bleeding was controlled as the patients were rushed to the operating room.

The graft in patient 3 had been removed 2½ months previously because of venous thrombosis, 10 days after the transplantation. The reason for his hospitalization was persistent serous wound drainage. A few hours after admission he had a cardiac arrest after suddenly developing abdominal pain and distention. The diagnosis was obvious, and the patient was resuscitated as he was brought to the operating room.

Patient 4 presented with upper gastrointestinal tract bleeding 1 year after graft pancreatectomy for pancreatitis. Upper and lower gastrointestinal tract endoscopy, technetium bleeding scanning, ultrasound examination, and arteriography of the abdominal aorta and iliac and visceral arteries did not reveal a bleeding source. She was discharged. Two months later, another episode of massive upper and lower gastrointestinal tract bleeding occurred. She was readmitted and collapsed within a few hours. At emergency operation, a rupture was found of the arterial anastomosis site into the tip of the Roux-en-Y loop previously used for enteric drainage.

Bacterial Cultures

The bacteria cultured from the rupture sites are listed in the Table. Results of cultures were negative in patient 4 but were considered to be falsely negative because there was communication with the intestine.

Surgical Treatment

All patients underwent ligation of the proximal and distal common iliac artery. In all but patient 4, crossover femoral-femoral bypass was performed immediately. In patient 4, the extremity seemed well perfused, and the limb was not revascularized. Ten months later, she developed intermittent claudication in the left leg. At the time of this writing, she is scheduled for arterial bypass.

The patients are all alive and well and are currently receiving exogenous insulin. Renal function, if it was present before, was not adversely affected by the complication (Table).

COMMENT

Since the advent of immunosuppression with cyclosporine, 1-year graft survival has improved and is currently reported to be 50% or more.[1-6] Breakdown of the constructed anastomoses for exocrine drainage has been common and has often been ascribed to the proteolytic activities of the pancreatic juices, or less often to infections.

Both factors could have contributed to the aneurysm formation and rupture in our four patients. The bacteria cultured from the rupture site in three patients were indigenous to the gastrointestinal tract, and in the patient with a negative culture, the rupture was into the intestine. Thus, we classified all of the pseudoaneurysms as mycotic.

Mycotic aneurysm and rupture may be a relatively specific complication of whole pancreas transplantation. Although Carrel patches to the iliac vessels are almost always used for kidney transplantation at the University of Pittsburgh, only one mycotic aneurysm was observed after 1375 cadaveric

Clinical Characteristics of Patients With Arterial Aneurysms After Pancreatic Transplantation*

Patient/ Age, y/Sex	Time of Kidney Transplant	Time Between Pancreas Transplant and Removal	Aneurysm Rupture, Time After Pancreas Transplant Graft Removal	Findings	Arterial Site Culture Results	Repair	Current Status
1/30/M	Previous	15 mo (rejection)	5 d	Pseudoaneurysm of LCIA	*Citrobacter freundii, Bacteroides melaninogenicus, Enterobacter aerogenes, Clostridium subtermindi*	Femoral-femoral, bypass ligation of LCIA	Alive and well; functional kidney transplant
2/28/M	Previous (10 nonfunctional transplants)	2.5 mo (rejection)	1 wk	Pseudoaneurysm of LCIA	*Bacteroides fragilis, Fusobacterium nucleatum*	Femoral-femoral, bypass ligation of LCIA	Alive and well; dialysis
3/36/M	Simultaneous	10 d (venous thrombosis)	2.5 mo	Pseudoaneurysm of LCIA	*C freundii,* microaerophilic philic strept *Viridans*	Femoral-femoral, bypass ligation of LCIA	Alive and well; functional kidney transplant
4/24/F	None	3 wk (pancreatitis)	14 mo	Pseudoaneurysm of LCIA	Negative	Ligation of LCIA	Alive and well; native renal function

*LCIA indicates left common iliac artery.

renal transplantations between 1981 and 1988. In contrast, mycotic aneurysms developed after 4 of our 17 whole pancreas transplantations between 1983 and 1986. At the University of Iowa, Iowa City, aneurysm rupture was seen in 3 of 80 cases (Robert Corry, MD, oral communication, September 1988). The same incidence of 3 in 80 cases has been seen at the Karolinska Institute in Stockholm (Carl G. Groth, MD, oral communication, September 1988). In all 10 cases of the Pittsburgh-Iowa City-Stockholm collection, exocrine pancreatic drainage had been into the gastrointestinal tract. This complication was not seen in 3 other patients in our series who had failed grafts removed. Two of these patients' grafts were grossly infected. A fourth patient has had a failed graft left in situ for 3 years without this complication.

Intraperitoneal placement of the pancreatic allograft offers a theoretical advantage of having the arterial anastomosis exposed to the peritoneal cavity rather than the closed extraperitoneal space. Patient 4 had the only intraperitoneal pancreas graft in our series.

Whether this frightening complication will be minimized with the increasingly popular techniques of exocrine drainage into the less contaminated bladder[8,9] remains to be seen. Walstra et al[10] have reported a successfully treated mycotic aneurysm after bladder drainage, which has also been observed with a fatal outcome (D. Nghiem, MD, oral communication, June 1988)

The most important lesson from this cumulative experience is the necessity for a high index of suspicion in the event of wound complications, unexplained shock syndromes, gastrointestinal tract hemorrhage, or unexplained abnormalities with examination performed physically or by imaging techniques. Appropriate surgical care then can be planned, sometimes electively instead of under the catastrophic circumstances that existed in all of our cases. In our patient 4, in whom a wound infection with *Candida stellatoidea* and *Candida albicans* was documented at the time the pancreas was removed for pancreatitis, prophylactic ligation of the common iliac artery was seriously considered but not done. This proved to have been an error when the aneurysm ruptured into the intestine more than 1 year later.

This study was supported by the Veterans Administration, Pittsburgh, Pa; grants DK-29961 and RR0005625 from the National Institutes of Health, Bethesda, Md; and the E. Clarence Rice Fellowship of the American Diabetes Association, Washington, DC (Dr Carroll).

Editorial Comment

This concise article describes a devastating complication (mycotic aneurysm at the arterial suture line) that has occurred with surprisingly high frequency in patients with pancreatic transplantation at the University of Pittsburgh. There have also been a significant number of identical complications reported by the Iowa City and Stockholm groups. The common denominator in all of these cases has been drainage of the pancreatic secretions into the gastrointestinal tract. There is little general recognition even in the transplant community as to the prevalence of this complication, even though the danger of gastrointestinal tract contamination in the immunosuppressed patients is well known. The authors' recommendation for a high index of suspicion of this complication and for its aggressive treatment by ligation of the iliac artery and extra-anatomic bypass is well taken, as is their suggestion that ligation of the artery should even be considered prophalactically in instances where contamination of the suture line is recognized.

Results of Operative Treatment of Gastrointestinal Tract Tumors in Patients Over 80 Years of Age

Ph. Morel, MD; R. A. Egeli, MD; S. Wachtl, MD; A. Rohner, MD

• Between 1981 and 1986, 140 patients over 80 years of age were operated on for a gastrointestinal tract tumor in our service. There were 24 gastric, one small-bowel, 91 colonic, and 24 rectal cancers. Only 40% of the patients were preoperatively free of any systemic disorder other than tumor. We performed surgical procedures with a curative intent for 90 (64%) of them. Our mean overall postoperative mortality was 17%, but this rate could be decreased by performing elective operations on well-prepared patients. Over 80% of the deaths were related to systemic organ failures. Eighty-three percent of the survivors (96 patients) returned to their homes; 82% (94 patients) had normal activities for their age. The actuarial survival curve showed a 50% survival rate at three years, all tumoral stages included. These results support the view that surgery is a safe, valid option in the face of gastrointestinal tract tumors in the elderly.

(*Arch Surg* 1989;124:662-664)

Various factors, including preventive medicine, medical progress, and improved social conditions, have increased life expectancy in our societies, and the elderly population continues to expand. Between 1900 and 1970, the general population worldwide multiplied by 2.5, whereas during the same period the geriatric population increased sevenfold. At present, the geriatric population comprises 11% of the general population. This proportion will increase in the coming decades.[1]

Among the causes of death in the geriatric population, cancer represents 15%, being the second leading cause after heart diseases (45%). In the group with cancer, colorectal cancers rank first for women and third for men after lung cancer and prostate cancer. Gastric tumors occur less frequently, and their incidence will decrease over time.[2]

In accordance with these figures, we often face the problem of treating a gastrointestinal tract tumor occurring in an older patient. Since surgery is the main therapeutic option for gastrointestional cancers, we must consider this option for geriatric patients. The surgical approach is dependent on the incurred risk, the tumor's extension and probable evolution, and the agreement of the patient. Other factors should also be taken into consideration, such as life expectancy and quality of survival.

The aim of this study, conducted in a university hospital with surgeons in training, was to assess the morbidity and mortality related to surgical treatment of gastrointestinal tumors in patients older than 80 years and to establish the quality and length of their survival.

MATERIAL AND METHODS

From January 1981 to December 1986, we prospectively studied 140 patients older than 80 years operated on for gastrointestinal tract tumors in the Service of Digestive Surgery, Geneva University Hospital. The criteria for inclusion in the study were as follows: patient aged 80 years or more at the time of operation; histological proof of a malignant tumor originating from the digestive tract from stomach to rectum; performance of a laparotomy with or without tumor resection; and no previous digestive tract tumor.

We surveyed 56 men and 84 women. The mean age at operating was 85 years (range, 80 to 94 years). Ninety-eight patients (70%) were between 80 and 84 years, 35 (25%) were between 85 and 89 years, and seven (5%) were over 90 years of age. Sex division among these age groups was similar.

We observed 24 gastric, one small-bowel, 91 colonic, and 24 rectal cancers.

According to the International TNM classification, the gastric cancers were divided as follows: two at stage I; six at stage II; seven at stage III; eight at stage IV; and one not classified. Following Dukes' classification for the colonic cancers, we had two Dukes' class A, 52 Dukes' class B, 25 Dukes' class C, and nine Dukes' class D; three patients could not be classified properly. For rectal cancers, we had two Dukes' class A, nine Dukes' class B, four Dukes' class C, five Dukes' class D, and four not classified.

The number of patients operated on every year does not vary significantly, and ranges from 20 to 29 per year.

The preoperative evaluation of the surgical risk was assessed by using the classification of the American Society of Anesthesiology (ASA), dividing the patients into five groups[3] as follows: 56 patients (40%) in class II; 64 (45%) in class III; and 11 (8%) in classes IV and V. Nine patients could not be classified because some data were not available preoperatively.

Our surgical intent based on a previous retrospective study[4] was to perform operations with a curative view every time that it was technically possible. We tried at least to resect the tumor itself, even if not carcinologically. We performed an operation with a curative view for 90 patients (64%), as 48 (34%) were submitted to an obvious palliative procedure (internal bypass, proximal stomy, or incomplete resection of a macroscopically disseminated disease). Figure 1 summarizes the operative procedures performed.

All survivors were assessed by contacting either them or their families, as well as their physicians. We were mainly interested in the quality of their survival. This appraisal was based on both their social postoperative environment after leaving the hospital and on their possible activities. For this last criterion, we used the activity index proposed by the Swiss Group for Clinical Cancer Research (SAKK).[5] It divides patients into five groups as follows: 0, normal activity; 1, normal activity with symptoms; 2, marked decrease of autonomy (<50% of the day in bed); 3, important decrease of autonomy (>50% of the day in bed); and 4, bedridden. The length of survival was also established.

RESULTS

Our overall postoperative *mortality*, defined as death occurring during the hospital stay, was 17% (25 patients)

(Table). Cardiac (12 cases) and pulmonary (ten cases) insufficiencies accounted for most deaths. We observed one brain stroke. Two patients died following septic complications related to intra-abdominal collections, one due to an anastomotic leakage. (We rarely used the facilities of the intensive care unit due to unsuitable local conditions.)

We observed a good correlation between preoperative evaluation with the ASA score and our postoperative mortality. The 56 patients in class II had a 10% mortality (six cases), the 64 in class III had an 18% mortality (12 cases), and the 11 in classes IV and V had a 36% mortality (four cases). Emergency operations, performed mainly for occlusive colonic cancers, induced a higher mortality (Table).

Postoperative morbidity applied to 21 patients (18%). Most of the complications (14 cases) were related to systemic disorders (pulmonary, cardiac, and neurologic). Seven were due to local problems (two small colonic anastomotic leakages and five septic wound problems).

The mean hospital stay was 17 days (range, six to 44 days), with a median of 15 days. After leaving the hospital, most of the patients immediately returned home (43 cases). The others convalesced either in a specialized home (39 cases) or in a medical recovery center (33 cases). Later, 83% (96 cases) of all patients had returned to their homes without any change in their social environments. A few (14 cases) had to be moved to a specialized institution or to a nursing home, since some (five cases) required nursing assistance at home or went to the family's home.

We compared the preoperative index activity with the postoperative index activity. Fifty-six (49%) of our patients belonged to class 0 preoperatively, 45 (39%) were in class I, ten (9%) were in class II, and four (3%) were in class III. Postoperatively, 94 patients (82%) were in class 0, 16 (14%) were in class I, four (3%) were in class II, and one (1%) was in class III. Thirty-eight patients shifted from classes I and II toward class 0 after removal of the tumor.

We can confirm that most of these elderly patients became independent following surgery and that they enjoyed their survival time.

The length of survival appears to be an important criterion in this age group, and we were pleased to note that the actuarial survival curve (Fig 2) shows a survival rate of 48% at three years (55 patients) and a rate of 32% at five years (37 cases), all stages of tumor development and all localizations included. At the time this report was written, 48 (42%) patients were alive with no evidence of disease, seven were alive with a documented recurrence, 39 (34%) were dead of disease, and 21 were dead of other causes. The mean survival time was three years two months (range, six months to five years eight months). The survival time correlated satisfactorily with the carcinologic stage of the disease. For colonic cancers, the survival rates for patients with Dukes' class B and Dukes' class C tumors were 65% and 26%, respectively, at three years. For patients with gastric cancers, we had an overall 31% survival rate at three years. In this group, the prognosis is slightly better for localized tumors.

COMMENT

Surgery on elderly patients is a continuous challenge. Operations performed for cancer on patients over 80 years of age can seem excessive, and the discovery of a gastrointestinal tract tumor at this age always raises the question of whether to perform a surgical resection. The challenge is to allow the patients to survive the operation and then to offer them a decent quality and length of survival.

With age, the general physiological capacities of the organism change progressively.[6] Our survey shows that over 50% of the elderly coming to surgery for tumor resection have an impairment in their various organ systems[7,8] not related to the effects of the tumor itself. The relationship between preoperative general health and postoperative outcome has been demonstrated[7,9-11] and appears in our survey, as the mortality rose from 10% to 36% from ASA class II to ASA classes IV and V. We therefore recommend that the various organic systems be carefully assessed preoperatively so that any deficiency or disorder can be detected and corrected or at least improved.[10] This assessment concerns mainly metabolic disorders, nutritional defects,[12,13] and cardiopulmonary abnormalities.[14]

This management cannot be applied to emergency surgical procedures, which therefore must be avoided whenever possible. A preoperative delay for resuscitation is required.[11] This preparation decreased the mortality from 26% to 16% in our survey when the results of emergency procedures were compared with the results of elective operations.[15-17] This relationship between the timing of an operation and the postoperative outcome is also encountered in the younger population.[9]

In the elderly, the immediate postoperative course is of great importance[10,15] and prompt detection of any organic failure is required. The use of an intensive care unit for at least 48 hours is recommended.[17]

Our overall 17% mortality is within the reported range of 6% to 20% for elderly patients.[7,17-20] Systemic disorders accounted for 88% (22 cases) of those fatalities, with the number of local intra-abdominal fatal complications being low.[15] We must point out that, in this age group, the risk factors for surgery for gastrointestinal tract tumors is the same as for other major surgical procedures, such as thigh amputation or hip-joint operations.[9,21]

The postoperative morbidity is also mainly related to systemic disorders (75%). Local anastomotic leakage or septic complications have the same low incidence as for younger people.[18]

Our option to attempt a curative resection whenever possible was successful in as many as 64% of our patients. From our previous study,[4] we estimated that it would prolong the length of survival and improve its quality. Even in the elderly, it is recommended that some operative time be spent to achieve this goal, as the length of the operation is not related to the postoperative outcome,[20] although some controversy remains about this attitude.[21] If a curative resection cannot be achieved, we always favor at least a tumor resection, even palliative, rather than a proximal diverting stoma. At this age, patients have difficulties in managing a stoma bag properly,[18] and the bag does affect their psychological well-being. A one-stage procedure with immediate anastomosis is the best option, and it can be achieved even in occlusive colonic tumors by using "on-table" cleansing of the colon.

The elderly can still enjoy life. Surgical treatment of gastrointestinal tract tumor will prolong their survival, as illustrated by our 50% survival rate at three years. This result correlates with other data[18,22] and illustrates the fact that the long-term prognosis for patients with resected gastrointestinal tract tumors is similar in all age groups.[23,24]

The quality of survival is of major importance in this age group: it would be unjustifiable to recommend an aggressive surgical approach in the elderly if the results were to dramatically alter the course of life. Our survey tends to prove the opposite. The hospital stay is short (mean, 17 days). The index of activity demonstrates that 82% of our patients spent an active normal life and could carry on their previous physical and social activities following surgery. Unexcised growing tumors would have resulted in major discomfort in terms of pain, complications, and debility. Moreover, 83% of the patients returned to their homes, though several spent some convalescent time elsewhere before returning. This issue is important, since the elderly feel secure if they can return to their preoperative environment.

Aggressive surgical treatment of gastrointestinal tract tumors in the elderly will, of course, lead to fairly high health care costs, and it is a matter of health policy to decide whether this cost is worthwhile.[25] Schelling[26] pointed out that the quality of survival should be taken into account at any age when establishing the cost-value relationship in health care. From our encouraging results, we learn that the elderly can well tolerate the attempt of a surgical resection of their gastrointestinal tract tumors. For most of them, it will prolong a worthwhile survival.

Surgical Manipulation and the Tensile Strength of Polypropylene Sutures

Philip B. Dobrin, MD, PhD

• Laboratory studies were performed on 509 size 6-0 polypropylene sutures to examine the effects of surgical manipulation on suture tensile strength. Results showed that dragging sutures over the torn edge of the foil package, permanently kinking sutures, or axially twisting them up to four times did not decrease tensile strength. Similarly, the tug exerted by operating room nurses on polypropylene sutures did not decrease their tensile strength. Two manipulations, however, did decrease breaking strength. The presence of a stray knot reduced suture strength 17%, and grasping sutures with DeBakey forceps decreased suture strength in a dose-dependent fashion. When experienced surgeons grasped sutures with forceps out of direct vision, their grasping forces were well below that which alters tensile strength. Nevertheless, these results demonstrate that sutures that have acquired a stray knot should be discarded and that sutures should not be grasped with mechanical devices such as forceps.

(*Arch Surg* 1989;124:665-668)

The adequacy of a suture depends on the strength of the filament relative to the load placed on it. For most surgical applications, sutures have sufficient strength to sustain the load applied to them with an adequate margin of safety.[1,2] This is especially true of polypropylene, which shows virtually no decrease in tensile strength following prolonged exposure to load and to tissue fluids.[3] Occasionally, however, sutures break,[4-11] raising the possibility that they may have been damaged during surgery.[10,11] Intraoperative manipulation of sutures can alter them structurally,[12,13] and it is presumed that this also weakens them mechanically. This is especially of concern in the case of monofilament sutures, where all the mechanical strength resides in a single strand.

The purpose of this investigation was to examine the extent to which surgical manipulation alters the breaking strength of 6-0 polypropylene sutures. This is of particular interest since recent evidence suggests that most of the strength of polypropylene sutures may lie in their outer "skin" rather than in the "core" of the filament.[14]

Accepted for publication April 14, 1988.

Reprints not available.

MATERIALS AND METHODS

Short segments of new 6-0 polypropylene sutures were prepared by placing 1-cm-long chains of square knots near both ends of the segments. A 4- to 5-cm-long region was maintained without knots between the chains at the two ends. The knotted chains were placed in clamps with soft plastic jaws to hold the suture segments firmly. One clamp was rigidly connected to a calibrated force transducer, and the other clamp was mounted on a nonrotating blade micrometer (Fig 1). The micrometer was manipulated to extend the suture in 0.25-mm increments and was held at each length for 10 s. This stepwise lengthening process was repeated until the suture broke. In all cases, the sutures broke where the straight portion of the filament entered the knot or where they were deliberately injured. In no case did the sutures break where they were held by the clamps. All experiments were performed in air at room temperature after it was demonstrated that there was no measurable difference in acute breaking strength for sutures studied dry at room temperature as compared with those studied in buffered physiologic salt solution at 37°C, pH 7.4.

Foil Abrasion

When sutures are removed from their foil package, the filaments may be dragged across the torn edge of the foil, which may damage the suture. To evaluate this, 28 polypropylene sutures were carefully removed from their foil packages. Fourteen sutures were dragged forcefully over the torn edge of the foil. Fourteen others were not subjected to contact with the foil to serve as controls. Chains of knots were placed at each end of the suture segments. Each segment was mounted in the soft-jawed clamps (Fig 1) and was extended in 0.25-mm steps until it broke.

Kinks and Knots

When sutures are removed from their package, the filaments may be inadvertently kinked or knotted. To examine the effect of kinks and knots, 54 polypropylene sutures were prepared for study by placing chains of knots at both ends of each segment. Eighteen segments were designated as control sutures. Eighteen others were folded and then rolled firmly between the thumb and forefinger to produce a visible, permanent kink in the knot-free region of the suture. Eighteen others were prepared by placing a single-throw knot in the usually knot-free region between the chains of knots. This was done to simulate the occasional stray knot, which may be formed as the suture is removed from the package. Each suture then was tested for tensile strength.

Nurses' Tugs

Some operating room nurses tug briefly on polypropylene sutures to remove their accordionlike folds. These folds are

Fig 1.—Apparatus used to extend sutures in steps to breakage (from Dobrin[2]).

Fig 2.—Method used to measure grasping force exerted by surgeons.

acquired by the suture from having been wrapped for a prolonged period around the cardboard package insert. Experiments were performed to evaluate the force exerted by the nurses' tugs. Eight experienced scrub nurses were studied in the laboratory. Polypropylene sutures were tied to force transducers. The nurses were instructed to tug on the suture just as they would in the operating room. Forces were recorded out of direct vision of the nurses. The mean (±SEM) tug force recorded was 89±8 g. The mean rate of tug exerted by the nurses was recorded to be 130 g/s, with durations of 1 to 4 s.

Experiments then were performed to determine whether the nurse's tug weakens the suture. One hundred sixty polypropylene sutures were prepared with chains of knots at both ends. One hundred forty-four suture segments were subjected to single tugs exerted at 129 g/s. Forces up to 450 g were applied. Sixteen other sutures were studied as controls. The sutures were then mounted in the test apparatus and extended in steps until they broke.

Axial Twist

During construction of an anastomosis, the needle may be grasped and regrasped with the wrist oriented in different ways, and this may axially twist the suture. Studies were performed on 100 polypropylene suture segments to examine the effect of axial twist. Twenty 4-cm segments were not twisted. Twenty others were axially twisted once (360°), twice (720°), three times (1080°), or four times (1440°). Each suture was mounted in the clamps while twisted and was extended in steps until it broke.

Table 1.—Effects of Surgical Manipulation on Suture Strength

	Control Segments	Kinked Segments	Knotted Segments

Breaking force, g (mean±SEM)	339.3±12.3	323.9±11.6	280.7±10.2*

*Significantly different from control ($P<.05$).

Forceps Injuries

Grasping sutures with forceps may injure and weaken them. To examine this insult, 167 polypropylene suture segments were prepared for study with chains of knots at both ends. Four DeBakey forceps (three V Mueller forceps and one Pilling forceps) were mounted in a horizontal position, and polypropylene suture segments were draped between the jaws of the forceps 1 to 2 mm from their tips. A "pinching" force was applied for 3 s at the tips directly over the suture. Pinching forces were applied by hanging weights from the upper arm of the horizontally mounted forceps. Pinching forces used ranged from 0 g (control) to 5000 g. After these pinches, the sutures were removed from the forceps and were mounted in the test apparatus to measure their tensile strength.

After all these data were obtained, the forceps were mounted vertically. Stainless steel wires were wrapped around each arm of the forceps 1 mm from their tips. These wires were attached to force gauges (Fig 2). The wires were connected with enough slack to permit the arms of the forceps to be grasped and brought within 2 mm of closure. The subjective sensation to the surgeon was that of closing the forceps about a grasped object. Five experienced surgeons then were asked to close the forceps out of direct vision and were directed to "grasp subcutaneous fat." They did so without knowing that the forceps were not grasping tissue but actually were attached to force gauges. These experiments provided data on the force exerted by surgeons when forceps are grasped to produce a subjectively satisfactory force.

RESULTS

Foil Abrasion

Fourteen sutures that had been dragged over the cut edge of the foil package broke at 332.8±9.3 g (mean±SEM). This was compared with 14 control sutures that broke at 334.1±10.9 g. These data were not significantly different as tested by a noncorrelated t test.

Kinks and Knots

Table 1 compares the breaking stresses recorded for 54 polypropylene suture segments subjected to no manipulation (control), kinking, or the placement of a single stray knot in the center of the filament. Deliberately kinking sutures did not alter their breaking strength (P, not significant). However, placing a single knot in the middle of the usually unknotted region reduced the breaking force 17%. This decrease was statistically significant ($P<.05$), as tested by analysis of variance and Scheffé's test.

Nurses' Tugs

Eight experienced operating room nurses were studied in the laboratory as they tugged on 6-0 polypropylene sutures. Forces recorded were 89±8 g (mean±SEM), well below the usual breaking force (about 315 to 330 g).

Table 2 summarizes the effect of applying a brief, controlled tug in the laboratory to remove the accordionlike

Breaking force, g (mean ± SEM)	333.1 ± 9.1	318.7 ± 12.4	312.6 ± 12.1	319.4 ± 14.0	315.4 ± 0.5

folds from the suture. The rate of loading was 129 g/s. Table 2 shows that single, brief tugs did not greatly alter the tensile strength of sutures. In fact, because of the brevity of the tugs, it was possible to apply loads up to 450 g without breaking the sutures. This is about 150 g greater than usual breaking forces. The values shown in Table 2 were not significantly different from each other as tested by analysis of variance.

Axial Twist

Table 3 presents the results of axially twisting 100 polypropylene sutures 0, 1, 2, 3, or 4 times. Because this axial twist was imposed on a suture about 4 cm long, four twists are comparable to those that might occur if a suture were twisted with each passage of a needle across an anastomosis. The data shown in Table 3 demonstrate that there was no reduction in breaking force due to this manipulation even after four axial twists. These data were not significantly different from each other as tested by analysis of variance. Therefore, moderate axial twisting does not seem to decrease suture strength.

Forceps Damage

Figure 3 presents suture tensile strength plotted as a function of forceps pinching force for 167 polypropylene sutures. Means and SEs are shown. These data demonstrate that low pinching forces had little or no effect. However, after a threshold was encountered, there was a graded decrease in breaking force in a dose-dependent fashion. It also is evident that the Pilling forceps produced a greater decrease in tensile strength than did the V Mueller forceps. For the V Mueller forceps, all pinching forces greater than 1770 g produced a statistically significant decrease in breaking strength as compared with the unpinched control sutures ($P<.05$). The force required to just bring the arms of the V Mueller forceps together without exerting any measurable pinch was 278 g. For the

Fig 3.—Tensile strength of 167 6-0 polypropylene sutures following exposure to pinching forces with surgical forceps. Arrow is mean grasping force exerted by five surgeons.

Pilling forceps, pinching forces greater than 1000 g produced a statistically significant decrease in tensile strength as compared with unpinched control sutures ($P<.05$). The force required to bring the arms of the Pilling forceps together without exerting any measurable pinch was 125 g. Thus, for both the V Mueller and Pilling forceps, the critical pinching force was about six times that required to just bring the tips together. Although it was not the purpose of this study to compare forceps, it is evident that the injury potential varies with different forceps designs. Interestingly, the gripping surfaces of the two forceps could not be differentiated when they were palpated out of direct vision.

The mean force exerted by five surgeons when closing either brand of forceps was 269 ± 29 g. This is shown as the vertical arrow placed on the x-axis of Fig 3. Thus, the pinching force exerted by the participating surgeons was only about 20% of that necessary to decrease the strength of 6-0 polypropylene sutures. Although these findings do not encourage surgeons to grasp polypropylene sutures with forceps, it does suggest that gentle grasping of the suture may not decrease the strength of the filament.

Of all the surgical manipulations examined, only the presence of a stray knot and the grasping of sutures with instruments decreased the tensile strength of the sutures.

COMMENT

During the 1950s and 1960s, silk and polyethylene sutures were used for vascular anastomoses. However, when these sutures were loaded and exposed to tissue fluids for prolonged periods, they degraded and lost their tensile strength.[11] As a result, suture failure resulted in an alarming number of anastomotic disruptions.[15-19] Starr and coworkers[19] reported that 39 false aneurysms developed in 1330 peripheral vascular operations. Of these 39 aneurysms, 16 were associated with the fracture of silk, polyethylene, or Dacron sutures.

Currently, polypropylene has replaced silk and polyethylene sutures in vascular surgery, which has dramatically decreased the incidence of anastomotic aneurysms. In a review of 4214 patients who had undergone arterial reconstruction, Szilagyi and coworkers[20] found 205 cases of anastomotic aneurysms but concluded that suture failure was responsible for only 3.4% of disruptions. Similarly, Gaspar and coworkers[21] reviewed 2400 anastomoses or arteriotomy closures. Ten anastomotic false aneurysms developed after these procedures, but only one could be attributed to the failure of a polypropylene suture. It is

evident from these data that polypropylene is a strong material that retains its strength when exposed to load and tissue fluid. Therefore, those few cases of suture failure that do occur may result from manufacturing defects or from damage incurred inadvertently during surgical manipulation. In our studies of over 1000 polypropylene sutures, we have never encountered a defective one, although it is possible that they exist.

In the laboratory, stretched sutures usually break at a knot,[2,14] for at this point the filament crosses over itself, creasing its outer surfaces. However, when a filament is passed through living tissue in a running fashion, the filament may break anywhere along the continuous suture line. It will break at the region of highest concentration of stress, provided the local load exceeds the tensile strength of the filament. Polypropylene slides easily through tissue as it is being inserted. After a continuous suture line has been constructed, however, the filament is bound by friction at each loop. Because of this segmenting effect, the load can be distributed unevenly along the suture line. Evidence for this segmenting effect is the fact that pulling the end of the suture after completion of a continuous suture line usually will not tighten a distant loose loop. As a suture line is being constructed, the filament may break if it is pulled too forcefully in an attempt to snug a given loop. Similarly, if pulling the suture to snug the loop results in a force that is just less than the breaking force, it may fracture when subsequently subjected to pressure and tissue tension. If the suture is defective or is damaged by surgical manipulation, it may break at a lower than normal force.

The present experiments show that the presence of a stray knot or the application of a strong grasping force weakens 6-0 polypropylene sutures. These findings are consistent with the observation that the stiffness and tensile strength of polypropylene sutures correlate with the circumferential skin of the filament rather than with its core.[14] Published data demonstrate that surgical manipulation can result in gouges, shards, and creases in the suture surface,[11,12] and it generally is assumed that these morphologic changes are associated with significant changes in tensile strength. It is remarkable, therefore, that the present data showed little loss of tensile strength with usual surgical manipulations. Application of large compressive loads by pinching with DeBakey forceps does decrease the strength of the suture, but the forces required to do so are greater than that exerted by most surgeons. In any case, the present findings demonstrate that damage can result to sutures from careless handling. Specifically, they indicate that sutures that have acquired a stray knot should be discarded and that sutures should not be grasped with mechanical devices such as forceps.

New polypropylene (Prolene) suture samples were provided by Ethicon Inc, Somerville, NJ. No other support, direct or indirect, was provided by the manufacturer.

Thromboxane A_2-Receptor Blockade and Prostacyclin in Porcine *Escherichia coli* Shock

Erik Svartholm, MD, PhD; David Bergqvist, MD; Ulla Hedner, MD, PhD; June Ljungberg; Ulf Haglund, MD, PhD

• Septic shock was induced by intravenous infusion of live *Escherichia coli* in pigs to investigate the influences on central hemodynamic, coagulation, and fibrinolytic reactions by a thromboxane A_2 (TxA_2)–receptor blocker (BM 13.177; n = 6) and a prostacyclin analogue (iloprost or ZK 36 374; n = 7). The early pulmonary vasoconstriction following *E coli* infusion was attenuated, but not abolished, by BM 13.177. Only minor effects were seen after pretreatment with iloprost. Neither drug had any major effect on the coagulation and fibrinolytic activation. These results confirm that TxA_2 is an important, but not the only, mediator of early pulmonary vascular response in porcine septicemia and that neither TxA_2 nor prostacyclin is of major importance for the hemostatic reactions in this shock model.

(*Arch Surg* 1989;124:669-672)

Cyclo-oxygenase products of arachidonic acid cascade metabolism are involved in the circulatory changes in septic shock,[1-5] which include pulmonary hypertension, increased pulmonary vascular resistance (PVR), systemic hypotension, and decreased cardiac output (CO). Mean pulmonary arterial blood pressure (MPAP) and PVR increase early, coincident with the generation of thromboxane A_2 (TxA_2), detectable as the increased concentration of the stable metabolite thromboxane B_2 (TxB_2).[1,5,6] These pulmonary circulatory changes have been reported to be attenuated, but not abolished, with different TxA_2 synthetase inhibitors.[2,5-7] The pathophysiologic role of TxA_2 is still under debate. Prostacyclin (prostaglandin [PG] I_2) is also generated in septicemia, but according to some studies to a lesser extent and in a later period than TxA_2. Prostaglandin I_2 counteracts the platelet aggregation and vascular constriction induced by TxA_2.[1,8-11] The circulatory reactions in septicemia could be caused by an imbalance of the prostacyclin-TxA_2 ratio.[3,11,12] Such an imbalance could be one explanation for the inability of TxA_2 synthetase inhibitors to normalize the circulatory impairment in septic shock. Furthermore, the precise role of TxA_2 in the pathophysiology of sepsis-induced circulatory and hemostatic reactions is difficult to evaluate from synthetase inhibition studies alone, because in this situation other metabolites with a TxA_2-like action could be generated when this pathway is blocked,[2,13,14] and even small concentrations of TxA_2 could be enough to cause substantial effects.[13]

The aim of this porcine study of septic shock was to investigate if a TxA_2-receptor blocker (BM 13.177) could achieve a more complete inhibition of the vascular response in a standardized experimental septic model than the earlier used TxA_2 synthetase inhibitors. Our aim was to study if and how modulation of the TxA_2/PGI_2 balance by infusion of a prostacyclin analogue (iloprost or ZK 36 374) influenced this vascular response. As earlier studies in our laboratory have not shown any major effect by pretreatment with a TxA_2 synthetase inhibitor on the substantial activation of the coagulation and fibrinolytic systems in septic pigs,[15] we also wanted to investigate if these reactions could be modified by the TxA_2-receptor blocker, by the prostacyclin analogue, or by both.

MATERIALS AND METHODS

This experimental porcine septic shock model was described in detail earlier.[7,15]

Pigs of either sex weighing 18 to 25 kg were used. The animals were anesthetized with thiopental sodium (25 mg/kg of body weight intravenously [IV] for induction and supplemental IV infusion as needed to ensure anesthesia). The preparation included orotracheal intubation (Mallinckrodt cuffed tube, size 7) and mechanical ventilation with mixed room air and oxygen (Engström respirator, ER 300). Arterial and venous lines were established for recordings of central hemodynamic parameters, blood sampling, and infusions, respectively (Figs 1 and 2, Tables 1 through 3). Tracheal pressures were recorded through a catheter in the cuffed tube. Pulmonary vascular resistance (mm Hg × minutes × 1^{-1}) was calculated from the following ratio:

$$\frac{\text{MPAP} - \text{Pulmonary Wedge Pressure}}{\text{CO}}$$

Fig 1.—Mean arterial blood pressure and mean pulmonary arterial blood pressure before and after bacterial infusion in untreated animals (n = 7, circles) and in animals pretreated with either BM 13.177 (n = 6, squares) or iloprost (ZK 36 374) (n = 7, triangles). Values are given as means ± SE. Asterisks indicate statistical difference compared with animals given bacteria but no pretreatment ($P < .05$).

Total peripheral resistance (mm Hg × minutes × l^{-1}) was calculated as mean arterial blood pressure × CO^{-1}.

Arterial blood samples from the iliac artery were taken at intervals (Tables 1 through 3) for determination of polymorphonuclear leukocytes, platelets, hematocrit, blood gases, and for preparing plasma samples for detection of changes in the coagulation and fibrinolytic systems. The diagnostic methods of these analyses have been described in detail earlier.[15] The blood losses from the sampling procedure were compensated for with Ringer's solution approximately twice the volume of the aspirated blood. To study the concentration of TxA_2 and PGI_2 during the course of the experiments, blood samples were taken in some pigs chosen at random for assessment of the arterial concentration of the stable metabolites TxB_2 and 6-keto-$PGF_{1\alpha}$, respectively, before the induction of septicemia and 120 minutes afterward. The analyses were performed using a modified radioimmunoassay for TxB_2 as reported by Fitzpatrick et al[16] and a radioimmunoassay utilizing a nuclear kit for 6-keto-$PGF_{1\alpha}$ (New England Nuclear Corp, North Billerica, Mass). The limit of sensitivity was 0.5 pg per tube for TxB_2 and 3.8 pg per tube for 6-keto-$PGF_{1\alpha}$, and the specificity (% cross-reactivity) was 0.025% to 0.9%.

The dose of the TxA_2-receptor blocker and the PGI_2 analogue used in this study has previously been used and validated by others.[8,17-19] The effect of the TxA_2-receptor blockade was further investigated by analyzing, according to the method of Born and Cross,[20] the antiaggregating effect of the TxA_2-receptor blocker on pig platelets activated in vitro by collagen or adenosine diphosphate. The incubation concentrations of the TxA_2-receptor

blocker were equivalent to the relevant range of plasma concentrations obtained by the IV doses used in the present experiments (1 to 2.5 mg/mL) and an incubation time of six to 12 minutes.

Experimental Procedure

Septic shock was induced by an IV infusion of live *Escherichia coli* (10^9/mL; 1 mL/kg/min for two minutes and thereafter 1 mL/kg/h continuously) suspended in Ringer's solution.[7,15]

Eight pigs were used as sham controls. Twenty pigs given *E coli* were divided into three groups. One group (n=6) was pretreated with the TxA_2-receptor blocker BM 13.177 (10 mg/kg of body weight during three minutes (concentration, 25 mg/mL), starting 15 minutes before bacterial challenge, followed by an infusion of 0.3 mg/kg/min. Another group (n=7) was given the prostacyclin analogue iloprost (100 ng/kg/min, starting 15 minutes before the bacterial infusion) suspended in 12 mL of Ringer's solution per hour and infused at a rate of 0.2 mL/min. The third group (n=7) was given bacteria but no pretreatment (untreated sepsis). The control group (n=8) was infused IV with the same amount of Ringer's solution as bacteria received by the other animals. The sham control animals were observed for three hours without further treatment. Some of the results of the untreated sepsis and sham control groups have been published previously.[7,15]

Statistical Analyses

Data are expressed as means ± SE. For the overall statistical comparison between the different series, the Kruskal-Wallis (H-test) was used. The Mann-Whitney *U* test was employed for intergroup analyses, and the Wilcoxon matched-pairs signed-rank test was used for comparison within each series. *P* values less than .05 were considered significant.

RESULTS

Control animals were stable with respect to all cardiopulmonary hemodynamics recorded. After an initial increase in mean arterial blood pressure, all animals infused with bacteria developed severe hypotension that started about 30 minutes following the *E coli* infusion (Fig 1). Cardiac output was approximately 3.5 L × minutes⁻¹ in all series. In the untreated sepsis series, CO declined to a terminal level of 21% of the prebacteremic control values, and treatment did not significantly influence this pattern. The MPAP increased abruptly during the first three minutes after *E coli* infusion (250% ± 19% of preinfusion control values) in the untreated sepsis series and remained increased throughout. This reaction was attenuated and only transient in the animals pretreated with the TxA_2-receptor blocker, but it was not abolished completely (Fig 1). The animals pretreated with the prostacyclin analogue had the initial MPAP increase as the untreated animals infused with bacteria but attenuated pulmonary hypertension at eight and 60 minutes (Fig 1). The calculated PVR was significantly lower early in septic shock in animals pretreated with the TxA_2-receptor blocker ($P<.05$). Later, the PVR increased in all the animals infused with bacteria (Fig 2). Total peripheral resistance increased transiently the first 30 minutes in all the animals infused with bacteria ($P<.05$). The end inspiratory to expiratory airway pressure difference increased slightly following bacterial infusion but did not differ significantly between the bacterial groups. In the two pretreated groups, arterial oxygen pressure declined following the infusion of bacteria but later and to a lesser degree (Fig 2).

Hematocrit values remained stable in all series (range, 0.23 to 0.44). A pronounced reduction of the arterial concentration of polymorphonuclear leukocytes and platelets was demonstrated after bacterial infusion ($P<.05$, Table 1). There was no difference between the bacterial groups concerning the polymorphonuclear leukocytes, but the early decrease in platelets was less pronounced in the two pretreated groups (Table 1). The TxA_2-receptor blocker showed an antiaggregatory effect on pig platelets in vitro when added in the same concentration as was calculated from the IV doses given in the animals receiving the receptor blocker (aggregation calculated from the optical transmission was 45% ± 3% compared with 65% ± 3% in normal plasma, and the maximum slope on the aggregometric curve was 23 ± 2 vs 42 ± 3 mm/min, respectively; $P<.05$).

The hemostatic reactions are summarized in Tables 2 and 3. Decreased levels of antithrombin III, α_2-macroglobulin, prothrombin complex (Simplastin A), and α_2-antiplasmin were found in all pigs with septic shock (Table 2). Fibrinolytic activity on fibrin plates (Table 3) could be demonstrated in all three bacterial groups. This was a transient phenomenon in all animals infused with bacteria, with maximal activity between one and two hours. Fibrin monomers, formed by thrombin action on fibrinogen, appeared earlier in the untreated septic pigs compared with the pretreated bacterial groups (Table 3). Alterations of fibrinogen concentration were moderate (Table 3). The 6-keto-$PGF_{1\alpha}$ levels were not increased 120 minutes after bacterial infusion except in the group pretreated with the prostacyclin analogue (698% ± 249% of the preinfusion value).

No hemodynamic or hemostatic influences by the TxA_2-receptor blocker or prostacyclin analogue were seen before the bacterial infusion. The TxB_2 level increased following bacterial infusion (2000 ± 671 and 6040 ± 776 pg/mL at baseline and 120 minutes after *E coli* infusion, respectively; $P<.05$) irrespective of pretreatment.

All eight animals in the sham control group survived the three-hour experiment. In the untreated bacterial group, two of seven animals died before three hours, and the remaining five animals died at the end of this bacteremic period. All six animals pretreated with the TxA_2-receptor blocker survived the experimental period. In the group pretreated with the prostacyclin analogue, three pigs died abruptly at 30, 60, and 100 minutes, respectively, while the other four survived the three-hour period and were killed.

COMMENT

This porcine septic model induces hemodynamic changes qualitatively equal to those of previous studies in both pigs

and other species using endotoxins or live bacteria.[2,21-23] Inhibition of TxA_2 synthesis is known to attenuate these hemodynamic changes in septic shock.[2,5,6] Such results are also reported from the present model.[7] A complete normalization of circulation, however, has not been reported after TxA_2 synthesis inhibition in septic shock. This only partial circulatory restitution could be explained either by effects of small residual concentrations of TxA_2 or a metabolic "shunting" phenomenon, resulting in increased synthesis of other vasoactive PGs, endoperoxides, or both acting at the same receptor as TxA_2 but not being influenced by TxA_2 synthesis inhibition.[2,5,9,13,14] Because of the shunting after TxA_2 synthesis inhibition, prostacyclin is reported to be synthesized in increasing amounts,[2,13,14,24] which to some extent may explain the results from studies using TxA_2 synthetase inhibitors in septic shock.[5,14]

With the TxA_2-receptor blocker, we obtained an attenuating effect on MPAP and PVR in early sepsis, as was found in series using a TxA_2 synthetase inhibitor.[2,7] Earlier investigations have shown the specificity and site of action of this TxA_2-receptor blocker and validated the dosage used in this series as relevant for a complete blocking effect.[17-19] Studies with cyclo-oxygenase inhibitors, eg, indomethacin, have shown unaltered MPAP and PVR in early sepsis, indicating that prostanoids other than TxA_2 are involved.[25,26] Present results support that early pulmonary hypertension is mediated by arachidonic acid metabolites not acting on the TxA_2 receptor. After TxA_2-receptor blockade, the PVR increased slowly and was not significantly different from the values registered in the untreated bacterial group in the later septic phase, in accordance with studies using indomethacin or specific TxA_2 synthetase inhibitors, indicating that this later phase of disturbed pulmonary circulation is due to substances other than cyclo-oxygenase products of arachidonic acid.[2,7,25,26] Using this septic model, we have earlier shown that a protease inhibitor, aprotinin, has an attenuating effect on this later phase, indicating sepsis-induced protease activation as the mediating factor.[25] This was also confirmed in a small series with this model, in which a combined indomethacin-aprotinin pretreatment prevented early and late deteriorated pulmonary circulation (E.S., U.H., U.H., unpublished data, 1988).

Previously, increased and decreased plasma levels of 6-keto-$PGF_{1\alpha}$ following septicemia have been reported.[1,3] One explanation for these variations is suggested by Yellin et al,[11] who found differences in 6-keto-$PGF_{1\alpha}$ levels between periods of sepsis and septic shock. They demonstrated that the 6-keto-$PGF_{1\alpha}$ concentrations were unchanged from control values during sepsis in swine but increased significantly when the septicemia was aggravated into a shock state.[11] Our results, increased TxB_2 levels but unchanged 6-keto-$PGF_{1\alpha}$ levels, were obtained from plasma determinations performed at 120 minutes, when the animals were in a state of sepsis but before a severe shock state was established. Furthermore, Yellin et al reported the most pronounced disturbance of the TxB_2/6-keto-$PGF_{1\alpha}$ ratio in the sepsis period, with a more than twofold increase and normalized ratio in the shock phase.[11] A similarly increased ratio in the septic period was also seen in untreated sepsis in this study. Infusion of the prostacyclin analogue normalized the TxB_2/6-keto-$PGF_{1\alpha}$ ratio in the septic phase. However, this was not followed by significant differences in pulmonary vascular response (Figs 1 and 2). Thus, a disturbed TxA_2-prostacyclin ratio seems to be of minor importance for the recorded impairments of pulmonary hemodynamics.

This work was aided by grants 4502, 759, and 05477-088 from the Swedish Medical Research Council, Stockholm, the Medical Faculty of Lund (Sweden) University, Malmö (Sweden) General Hospital, Syskonen Svensson's Foundation, Malmö, and the Trygg-Hansa 80-Years Foundation, Stockholm.

The BM 13.177 was supplied by Boehringer-Mannheim Ltd, and the iloprost (ZK 36374) was supplied by Schering AG. The bacteria were provided by the Department of Clinical Bacteriology, Institute of Medical Microbiology, Lund University, Malmö General Hospital.

The thromboxane B_2 and 6-keto-$PGF_{1\alpha}$ determinations were done by the Ligand Laboratory, University Hospital of Michigan, Ann Arbor.

Inflammatory Aneurysms of the Abdominal Aorta

Hans H. Moosa, MD; Andrew B. Peitzman, MD; David L. Steed, MD; Thomas B. Julian, MD; Fredric Jarrett, MD; Marshall W. Webster, MD

• Inflammatory aneurysms of the abdominal aorta (IAAAs) have distinctive clinical and physical characteristics that separate them from typical atherosclerotic aneurysms. They were identified in 19 (7.2%) of 265 patients undergoing abdominal aortic aneurysm repair. Symptoms were present in 12 (63%) of 19, with one patient presenting with rupture, and multiple symptoms were present in six (32%). Intraoperatively, all aneurysms exhibited dense periaortic inflammation. Adjacent structures most frequently involved were the duodenum in 15 (79%) of 19 patients, the left renal vein in six (32%) of 19, and the ureter in five (26%) of 19. Seventeen (94%) of the 18 patients who underwent elective aneurysm resection survived. The involvement of retroperitoneal structures varied in number and severity, demonstrating that a wide spectrum of inflammation is present in IAAAs, making diagnosis and definition difficult.

(*Arch Surg* 1989;124:673-675)

The term *inflammatory aneurysm* was first coined by Walker et al[1] in 1972 to describe a group of 19 patients whose abdominal aortic aneurysm showed excessive mural thickening and adherence of structures adjacent to the aneurysm. The association between perianeurysmal fibrosis and ureteral obstruction has been described in a series of reports[2-12] originating with James' description in 1935.[2] Although several vascular surgeons have emphasized the unique clinical features of inflammatory aneurysms and the necessity for modifications in the surgical approach, the number of retroperitoneal structures involved and the extent of inflammation required to categorize an aneurysm as "inflammatory" have not been defined.[13-17]

Inflammatory aneurysms of the abdominal aorta (IAAAs) are variants of atherosclerotic aneurysms that have distinctive clinical and physical characteristics. Despite the gradual accumulation of experience in treating patients with IAAAs, this variant continues to present a diagnostic and therapeutic challenge to the vascular surgeon. The purpose of this study was to review the experience at the University of Pittsburgh to characterize further the clinical presentation, the severity of the inflammatory process, and the operative management of IAAA.

METHODS

The records of 265 patients who underwent repair of abdominal aortic aneurysm from 1970 to 1987 were reviewed. Inflammatory abdominal aortic aneurysms were identified in 19 patients (7.2%). Criteria for the diagnosis of IAAA were the intraoperative presence of perianeurysmal fibrosis, marked thickening of the aneurysm wall, and adherence of adjacent structures to the aneurysm. Follow-up data were obtained in all cases through outpatient evaluation and telephone conversations.

RESULTS

Nineteen (7.2%) of 265 patients with abdominal aortic aneurysms had inflammatory aneurysms. None were identified prior to 1979. There were 17 men and two women ranging in age from 53 to 81 years (mean, 65 years). Twelve patients (63%) presented with symptoms as follows:

Symptom	No. of Patients
Abdominal pain	7
Back pain	3
Flank pain	1
Obstructive uropathy	2
Tenderness	1
Rupture	1

Multiple symptoms were present in six patients (32%).

All patients were heavy smokers (mean, 44 pack-years). Hypertension was the most common associated finding, occurring in ten patients (53%). Additional associated diseases included coronary artery disease in three, diabetes mellitus in two, stroke in one, and cirrhosis in one. Preoperative diagnostic studies included angiography in 15 patients, sonography in ten patients, and computed tomographic (CT) scanning in five patients.

Intraoperatively, all 19 patients had perianeurysmal inflammation, with thick, dense, glistening fibrous tissue that often involved adjacent structures, as noted in the following tabulation:

Structure	No. of Patients
Duodenum	15
Left renal vein	6
Ureter	5
Inferior vena cava	2
Small intestine	1
Sigmoid colon	1
Inferior mesenteric vein	1

Control of the aorta was obtained below the renal arteries in all patients, except the single patient with a ruptured aneurysm. The left renal vein was divided in three patients. No involved bowel was dissected. Ureterolysis was performed on four patients, three of whom presented with obstructive uropathy while one had renal insufficiency. One patient had ureteral entrapment without elevation of serum urea nitrogen or creatinine levels and did not undergo ureterolysis. Cultures of the aneurysm obtained at operation were negative in all but one case in which group D streptococcus grew. No postoperative infections were seen. All aneurysms were resected, and the aorta was reconstructed with a prosthetic graft. Aortoiliac grafts were placed in 16 patients (84%), while tube grafts were used in the remainder.

The single patient with a ruptured aneurysm died of sepsis two months postoperatively. Seventeen (94%) of the 18 patients undergoing elective aneurysm resection survived. The single postoperative death was due to anaphylaxis from iodine contrast from an intravenous pyelogram two weeks postoperatively. Fifteen patients (79%) were alive six months to seven years after aneurysm repair (mean, 3.2 years). Deaths at one year and two years were due to myocardial infarction and lung cancer, respectively. In one patient, abdominal exploration for small-bowel obstruction four months after aneurysm repair showed resolution of the perianeurysmal inflammation.

COMMENT

Inflammatory abdominal aortic aneurysms have clinical characteristics distinct from ordinary atherosclerotic aneurysms, although the correlation with clinical symptoms is imprecise and makes preoperative diagnosis difficult. The inflammatory variant is more likely to produce symptoms of abdominal, flank, or back pain.[1,13-18] Eleven (58%) of our patients had pain as a primary complaint. Erythrocyte sedimentation rates (ESRs) were not measured in our series but may be elevated in some patients.[1,14,16,18] The triad of chronic abdominal pain, weight loss, and an elevated ESR has been described as highly suggestive of the inflammatory nature of an abdominal aortic aneurysm.[16]

Angiography does not demonstrate the presence of inflammation.[16] The most reliable preoperative investigation appears to be a contrast-enhanced CT scan.[15-22] In one series, CT scanning suggested the diagnosis in 50% of the patients, while ultrasonography identified it in only 13.5%.[16] Computed tomographic scanning may show a dense, thick, anterolateral mass of periaortic tissue lying outside the calcified media, with sparing of the posterior wall.[22] Of the five CT scans obtained in our series, four demonstrated the characteristic findings, although the diagnosis was not made preoperatively (Figure). One patient had a large retroperitoneal hematoma consistent with rupture. The inflammatory component is composed of hypervascular tissue and usually displays delayed enhancement following intravenous contrast treatment, while the thick fibrous adventitia does not enhance[22] (Figure). However, exaggerated contrast enhancement of the periaortic mass may occur and may have the same appearance as blood in the aortic lumen, leading to a mistaken diagnosis of rupture or aortic dissection.[20,23]

Computed tomographic scan of inflammatory aneurysms of abdominal aorta showing enhancement of thick inflammatory tissue involving arterolateral aortic wall (arrow). Note sparing of posterior wall.

Sonographically, an echo-free halo may be present around the aorta, corresponding to the fibrous tissue located anterolateral to the aorta. The aortic wall is not obliterated by the sonolucent rim of tissue that distinguishes aortic inflammation from other retroperitoneal structures, such as enlarged lymph nodes.[24] These sonographic findings have not been consistent in patients with IAAA.[16] Of the ten aortic sonograms performed in this series, no characteristics specific for IAAA were demonstrable, suggesting that thickening of the aortic adventitia may be subtle and may vary in severity, making preoperative detection by sonogram difficult.

Perianeurysmal fibrosis may cause ureteral entrapment and obstruction. The ureters are drawn toward the midline by the inflammation, unlike the lateral displacement seen with large atherosclerotic aneurysms. Disagreement exists about the need to perform ureterolysis on patients with ureteral obstruction.[11,12,15] We performed ureterolysis on patients who had ureteral entrapment associated with obstructive uropathy or renal insufficiency. Crawford et al[15] reported resolution of ureteral obstruction following aneurysm repair, suggesting that ureterolysis may not be necessary.

The diagnosis of IAAA is usually made at the time of operation.[13-17] Extension of the retroperitoneal process to involve adjacent structures is likely. Sixteen patients (84%) in this series had involvement of one to three adjacent structures, while only three patients had perianeurysmal inflammation alone. The posterior wall is often spared from involvement in the fibrotic process, making it the most likely point for rupture to occur.[17] One of our patients presented with a contained retroperitoneal rupture that occurred posteriorly. This was also the only patient in the series in whom aortic control was obtained at the diaphragm. Control may normally be obtained below the renal arteries, although occasionally division of the left renal vein may be required. Three of our patients required division of the left renal vein to allow exposure to the aneurysm neck, and none suffered postoperative renal complications. Dissection of the adherent duodenum or intestine is technically difficult, can lead to entry into the gastrointestinal tract, and should be avoided.[13] The repair

can then proceed by suturing the replacement graft from within the aneurysm.

The etiology of IAAA is unknown.[7] Rose and Dent[25] described a pathologic spectrum of inflammatory changes present in patients with IAAA. They suggested that these aneurysms are variants of the usual atherosclerotic aneurysm in which the chronic inflammation and fibrosis seen in response to atherosclerosis is accentuated.[25] Mitchinson[26] stated that the inflammation may be due to hypersensitivity antigens in the atheromatous plaque. Removal of the presumed stimulus for the exaggerated inflammatory reaction (the atherosclerotic plaque) should lead to resolution of the inflammation. Follow-up CT scans after aneurysm resection and after steroid administration have demonstrated resolution of retroperitoneal fibrosis.[12,15,27] Repeated CT scans in other studies have shown no improvement after aneurysm repair.[17] One patient in our series had no gross evidence of inflammation at subsequent laparotomy, suggesting that regression of retroperitoneal inflammation can occur after aneurysm repair. The etiology of IAAA and the response to operative intervention remain to be elucidated.

The variable extent of periaortic fibrosis seen clinically in this study suggests that a clinical as well as a pathologic spectrum of inflammation is present. Abdominal atherosclerotic aneurysms can be associated with an inflammatory fibrotic process that may involve up to several retroperitoneal structures or just the aortic wall itself. Inflammation associated with atherosclerosis and aneurysm formation may progress to a point where distinct physical features become evident. Aneurysms exhibiting any characteristic fibrotic process may be described as inflammatory, making definition and diagnosis of IAAA difficult.

The diagnosis of IAAA can be made preoperatively by the presence of symptoms and an elevated ESR in a patient with an abdominal aortic aneurysm. A CT scan with contrast exhibiting periaortic inflammation or involvement of adjacent structures is the most reliable diagnostic test. Modifications in the operative approach are dictated by the severity of the retroperitoneal inflammation and the adjacent organs involved. Resection of the aneurysm with prosthetic graft replacement is recommended and can be performed with excellent results.

Strategy in Reoperative Surgery for Hyperparathyroidism

Polly S. Y. Cheung, MBBS, FRCS; Anders Borgstrom, MD; Norman W. Thompson, MD

• Eighty-three patients undergoing reoperations for hyperparathyroidism were studied. Preoperative diagnosis was reviewed, and localization was employed in selected patients. Cervical reexploration was carried out in a systematic manner, and mediastinotomy was required in 11 patients. Sixty patients had had previous parathyroid exploration. Missed adenomas were found in 34, of which 28 were single and 6 were double adenomas. Fourteen single adenomas were in normal locations and 14 were in ectopic locations. Seventeen patients had hyperplasia; 6 were wrongly diagnosed as adenoma, 3 had inadequate excision, 2 had supernumerary glands, and 6 had remnant hypertrophy. Three patients had recurrent carcinoma. Two had wrong diagnoses and 4 had uncertain diagnoses. Reoperation eliminated hypercalcemia in 71 patients (85.5%). Eight patients developed permanent hypoparathyroidism, and 1 had a permanent recurrent nerve palsy. Reoperative parathyroid surgery can be minimized with thorough initial cervical exploration, correct pathologic interpretation, and adequate parathyroid resection.

(*Arch Surg.* 1989;124:676-680)

Primary cervical exploration for hyperparathyroidism by experienced surgeons is associated with a success rate of over 95% and is better than any localization procedures.[1-3] However, good results depend entirely on the experience of the surgeon and his or her knowledge of anatomy, embryology, and pathology of the parathyroid glands. Though many primary operations appear easy when the tumor is identified, failure in the initial operation poses a great problem for the reoperating surgeon. Because of scarring, tissue planes are often obliterated and the anatomy is distorted. Structures such as the recurrent laryngeal nerves are difficult to define. Both normal and abnormal parathyroid glands are obscured, and the blood supply to normal parathyroid glands may be jeopardized. Reoperative parathyroid explorations are therefore associated with increased chance of failure and a much greater risk of complications.

To identify the factors leading to failure at primary operation and to establish guidelines for managing reoperative parathyroid problems, we reviewed our experience with reoperations for hyperparathyroidism.

PATIENTS AND METHODS

Between 1970 and 1985, 754 patients who were operated on for primary or secondary hyperparathyroidism were evaluated. Eighty-three patients had had previous neck explorations for either thyroid or parathyroid disease. Twenty-three had had previous thyroid operations, 42 had persistent hypercalcemia after a primary operation, and 18 had recurrent hyperparathyroidism as determined by hypercalcemia recurring more than 6 months after the initial exploration.[4] There were 21 men and 62 women. Their ages ranged from 21 to 83 years, with a mean age of 54 years. Seventy-seven patients had primary and 6 had secondary hyperparathyroidism. In 3 patients, hyperparathyroidism was associated with multiple endocrine neoplasia type I or II syndrome.

Evaluation Before Reexploration

The diagnosis of hyperparathyroidism was reviewed in every patient, and the clinical symptoms were assessed. Inquiries were made about a family history of hypercalcemia or multiple endocrine neoplasia syndromes. Serum calcium, phosphorus, and parathyroid hormone concentrations were measured to redetermine the diagnosis. Urinary calcium levels were also determined to rule out the possibility of familial hypocalciuric hypercalcemia.

The operative notes and pathology reports of the previous operations were studied, taking note in particular of the following points: number of parathyroid glands visualized and subjected to biopsy; location and pathologic features of the resected parathyroid glands; and status of the thyroid gland, ie, any resection in search of missing parathyroids. The locations of the parathyroid glands identified or removed were scrutinized in relation to the thyroid lobe surfaces, recurrent laryngeal nerve, and inferior thyroid artery to determine whether they were superior or inferior glands. Adequacy of exploration and technique of removing tumor were assessed, taking note in particular of any breach in the capsule of the tumor. Histologic slides of the previous resected specimen were reexamined. The side of the neck bearing the missing gland, its embryologic origin, and its possible location were determined.

Patients who were determined to have had an adequate initial cervical exploration underwent localization studies before reoperation. Selective arteriography and venous samplings were em-

ployed in the early part of the series. Computed tomography, ultrasonography, and thallium-technetium isotopic scanning were used when they became available. Subsequently, only noninvasive studies were done if the result of localization was positive.

Operative Approach

Cervical exploration was chosen when the diseased gland was suspected to be in the neck. The side of the neck to be explored first was determined from the analysis of operative notes and localization studies. The previous neck incision was used in all cases, after which the standard skin–platysmal muscle flaps were developed. For exploration of missing superior glands, an incision was made along the anterior border of the sternocleidomastoid muscle, lateral to the strap muscles (lateral approach). The lateral and posterior aspects of the thyroid gland were mobilized and the space between the pharyngoesophagus and the prevertebral fascia was explored from the carotid bifurcation down to the posterosuperior mediastinum. When the inferior gland was missing, the lower portion of the strap muscles were split in the midline (medial approach), and dissection was followed from the lower pole of the thyroid gland along the thyrothymic tract to the thymic tongue into the anterior mediastinum. When no abnormal glands were identified after a thorough exploration, cervical thymectomy was performed.

When localization studies suggested a mediastinal lesion, a cervical approach was attempted for lesions above the aortic arch. If neck exploration failed to uncover the abnormal parathyroid or the lesion was localized too low in the mediastinum, further exploration was performed through a median sternotomy or thoracotomy.

The reexploration was terminated when the abnormal gland was identified and removed. Any remaining normal parathyroids were not sought, so that their blood supply would not be jeopardized by further mobilization through the scar tissue.

RESULTS

A total of 92 reoperations were performed on 83 patients. Seventy-seven patients were operated on once and four twice; one had three and another had four reoperations. Of those with multiple reoperations, three were cured but three were not, two because of recurrent carcinoma and one due to recurrent hyperplasia. An operative approach by the cervical route was chosen in most cases. Sternotomy was required when localization studies indicated a mediastinal lesion. The operative approaches were as follows.

Approach	No.
Cervical	81
Lateral	49
Medial	25
Lateral + medial	5
Strap muscles excision	2
Cervical + sternotomy	9
Sternotomy	1
Anterior thoracotomy	1
Total	**92**

Localization procedures were attempted in 36 patients and were helpful in 14 patients. Among the various modalities, thallium-technetium scintiscanning was the most accurate (Table 1).

The final diagnoses reached after reoperation are shown in Table 2. In the group with persistent hyperparathyroidism, 32 patients had missed adenomas. Sixteen were superior and 16 were inferior gland adenomas. Of the missed superior gland adenomas, 9 were in normal locations and 6 were in aberrant locations (including 1 retropharyngeal, 3 retroesophageal, and 2 in the tracheoesophageal groove). Only one was truly ectopic, buried in the esophageal wall above the level of the inferior thyroid artery (Fig 1). Of the missed inferior gland adenomas, 1 was in the thyrothymic tract, 2 were intrathyroidal, 4 were in the thymic tongue, 4 were in the mediastinal thymus, 4 were in the mediastinum at the root of the great vessels, and 1 was lying within the pericardium at the root of the superior vena cava (Fig 2). The median size of the missed glands was 2 cm, with a range of 0.5 to 7 cm in the longest diameter. Among these 32 missed adenomas, 2 were fifth-gland adenomas, found after 4 normal glands had been identified during the first exploration. Four were second ("double") adenomas, 2 in normal sites for superior glands, 1 in the esophageal wall, and the other in the thymus. Two were missed because thyroid neoplasms were misinterpreted as intrathyroidal parathyroid adenomas on frozen section and the remaining parathyroid glands were not explored.

Five patients had persistent hyperparathyroidism due to hyperplasia. Three cases were caused by inadequate excision (two with asymmetric hyperplasia were incorrectly diagnosed as adenoma, and one had a missing inferior gland despite reoperation, probably in an ectopic site). One patient had an apparently adequate initial excision of 3½ parathyroid glands, but the presence of an overlooked supernumerary gland led to persistent hyperparathyroidism. One patient developed hypertrophy of the remnant, which grew to 1 cm in 6 months.

In the group with recurrent hyperparathyroidism, two patients developed a second adenoma. One occurred 2 years later, and the tumor was found in the thyrothymic tract. The other occurred 22 years later, and the tumor was located in the posterosuperior mediastinum. Both patients had undergone incomplete exploration at the initial operation. Twelve patients had recurrence due to hyperplasia: 4 had asymmetric hyperplasia incorrectly diagnosed as adenoma, 2 had inadequate excision due to unidentified glands (1 was found in the paraesophageal area, and the other was not found despite reexploration), 1 had a 1-cm supernumerary gland in the carotid sheath, and 5 had remnant hypertrophy (one of whom also had multiple endocrine neoplasia type I syndrome).

Three patients had recurrent parathyroid carcinomas, all incorrectly diagnosed as adenomas at the initial exploration. One had residual tumor invading the strap muscles and esophageal wall requiring local excision, subtotal thyroidectomy, and modified neck dissection. Another had seeding of tumor in the pharyngeal wall as a result of rupture of the tumor capsule during previous removal. The third patient had recurrent tumor along the tracheoesophageal groove in the posterosuperior mediastinum below the level of the original tumor.

Two patients were diagnosed as having other disease after reexploration. One had hypercalcemia suppressible by steroid therapy, and the other had repeated renal stone formation and hypercalcemia despite normal serum calcium and parathyroid hormone concentration. Four patients had doubtful diagnoses: two were found to have four normal glands, and the other two had one adenoma plus two normal glands at reoperation.

Hypercalcemia was eliminated in 71 patients (85.5%), and complications occurred in 31 patients (37.3%) (Table 3). One patient who had undergone four reoperations for recurrent carcinoma had permanent recurrent laryngeal nerve palsy and Horner's syndrome on one side and transient recurrent laryngeal nerve palsy on the other side. Another patient who developed a transient esophageal fistula had excision of recurrent carcinoma in the neck. The three pulmonary complications occurred in patients who had median sternotomies. Congestive heart failure occurred in one patient after dialysis for chronic renal failure. One patient had cardiac and renal failure secondary to hypercalcemic crisis. There was one operative

death; the patient died of pulmonary embolism 5 days after reexploration.

COMMENT

Missed adenomas are the cause of persistent hyperparathyroidism in 50% to 80% of cases.[5-7] A sound knowledge of the anatomic location of normal and ectopic parathyroid glands together with a systematic neck exploration would have uncovered most of the abnormal glands in the first operation. Often, a superior gland adenoma is missed when it is located under the dorsal surface of the thyroid gland. We have found that incising the fascia connecting the lateral border of the thyroid lobe to the carotid sheath (exposing the prevertebral fascia) allows adequate mobilization of the thyroid gland.[8] Its posterior aspect can then be completely visualized without the need for dividing the superior thyroid vessels. Six of the missed superior gland adenomas were quickly identified and excised after this maneuver. When the superior gland is not readily seen, incising the thyroid sheath may reveal a hidden parathyroid gland. This occurred in the remaining three patients with normally located superior gland adenomas missed by the first surgeon. Superior gland adenomas may be located aberrantly in the retropharyngeal and retroesophageal space, the tracheoesophageal groove, and down in the posterosuperior mediastinum.[9,10] Digital exploration of the prevertebral space behind the pharynx and esophagus may locate a parathyroid adenoma, which is usually felt as a soft, pliable, freely mobile mass in this location and can be easily removed by dividing the vascular pedicle from the inferior thyroid artery.

The positions of the inferior glands are more variable.[10,11] It is therefore important to explore systematically from the lower pole of the thyroid lobe, along the principal inferior thyroid vein or the thyrothymic tract to the cervical part of the thymus. Eight of the 11 missed inferior gland adenomas referred from other hospitals could have been found by following this approach. If an inferior parathyroid gland is still not found, a thyroidotomy in the lower pole of the ipsilateral thyroid lobe or excision of the lower pole is advised. One intrathyroidal parathyroid adenoma in our series was discovered in this way.

Apart from knowledge of normal, aberrant, and ectopic locations of the parathyroids, a complete exploration of all four parathyroid glands is important because of the possibility of double adenomas, asymmetric hyperplasia, or supernumerary glands.[12-17] In the four cases of double adenomas in our series, the second tumor was on the contralateral side of the neck. These were missed because only one side of the neck was explored. Two cases of asymmetric hyperplasia were also misdiagnosed as adenoma when only a unilateral exploration was carried out.

*RLN indicates recurrent laryngeal nerve.

Differences in glandular cellularity and intracytoplasmic fat staining, or the presence of a rim of normal parathyroid tissue around an adenoma, have been used to distinguish between adenoma and hyperplasia.[18] However, this is not totally reliable because in asymmetric hyperplasia, the parathyroid glands can exhibit great variation in glandular size and cellularity. Furthermore, the presence of a rim of normal parathyroid tissue around an adenoma is not a constant feature. Therefore, the final diagnosis relies greatly on the surgeon's judgment of the gross morphologic finding of all parathyroid glands at operation, together with the difference in the degree of glandular hypercellularity and amount of intracytoplasmic fat stain in the parathyroid glands. Complete neck exploration is thus important.

While removing an apparent adenoma, it is important to avoid breaching the capsule so that the chance of seeding hyperplastic parathyroid cells is minimized. It is especially important when the diagnosis of carcinoma is in doubt because spilling of malignant cells may lead to local recurrence, as illustrated by our two cases of recurrent parathyroid carcinoma.

Remnant hypertrophy is a major cause of recurrence in patients with hyperplasia, in our experience. This represents the natural course of primary or secondary hyperplasia. Block et al[19] reported a 14% persistence or recurrence rate after subtotal parathyroidectomy for multiglandular disease. Total parathyroidectomy with autotransplantation may be an alternative measure to avoid this recurrence.

Localization procedures before reoperation are particularly valuable when the previous cervical exploration is deemed complete. They can be especially useful in localizing mediastinal and intrathyroidal lesions and determining the side of the neck to be reexplored. However, the reported success rates of computed tomography, ultrasound, arteriogram, selective venous samplings, and thallium-technetium scan have varied widely from 36% to 85%.[20-23] These cannot replace an experienced surgeon with a systematic operative approach.[24] In fact, of the six mediastinal lesions removed via a median sternotomy or thoracotomy, only

three were localized preoperatively, and the remaining three were recovered after a meticulous dissection by the surgeon despite failed localization.

Our result showed that 64 (91.4%) of the 70 hyperfunctioning glands could be removed from the neck, and similar experiences have been reported by others.[2-6,25] Most upper mediastinal lesions can be retrieved from a cervical incision.[7,24] Median sternotomy or thoracotomy is rarely needed unless the mediastinal lesion is located beneath the aortic arch or the abnormal gland is not found in the neck after a thorough exploration by an experienced surgeon.

The lateral approach in cervical exploration described by Feind[24] has an advantage in reoperative cases where a superior gland adenoma is suspected. It allows for adequate exploration of the dorsal surface of the thyroid gland, the tracheoesophageal groove, retropharyngeal and retroesophageal space, and posterosuperior mediastinum, without having to dissect through the adhesions between the strap muscles and the thyroid lobe, especially when previous thyroidectomy has been done. If an inferior gland is missing, the strap muscles can be either split in the midline or divided near their insertion.

Our success rate of reoperation of 85.5% compares favorably with the 78% to 90% reported by others.[2-7] However, about half of these operations could have been avoided if the initial exploration had been adequate. Despite reoperation, the rate of transient or permanent recurrent laryngeal nerve palsy was acceptable. The risk of postoperative hypocalcemia is certainly increased by previous thyroid or parathyroid operations. It could have been avoided in most cases if normal parathyroid glands had not been excised injudiciously during the first operation and might have been prevented in others by autotransplantation of parathyroid tissues, even though they were hyperplastic tissue.[26]

CONCLUSION

Reoperative parathyroid surgery carries a higher failure rate and increased complications compared with primary operations. Its success relies on a careful preoperative review of the diagnosis and evaluation of the anatomic and pathologic status of the excised and remaining parathyroid glands. With the selective use of localization procedures and a systematic operative approach, recovery of the pathologic parathyroid tissue is assured in most cases. However, the need for reoperations can be minimized if the initial exploration is adequate, the pathologic type is correctly identified, and the extent of parathyroid resection is appropriate for the disease.

How Accurate Is Fine-Needle Biopsy in Malignant Neoplasia of the Pancreas?

Livingston Parsons, Jr, MD, Charles H. Palmer, MD

• The accuracy of fine-needle aspiration biopsy of the pancreas in 77 patients was studied, in 47 by the percutaneous route and in 30 under direct vision at the time of operation. Seventeen (49%) of 35 pancreatic malignant neoplasms were detected percutaneously and 13 (65%) of 20 at surgery. The predictive value of a positive test was 100% in both situations. The sensitivity of the percutaneous test was 57%; the sensitivity of the test done at operation rose to 72%. No complications were encountered. The test, when positive, can be relied on in surgical decision making but is of limited value when negative. Our findings are essentially similar to those of others who have reported their experience in the literature.

(*Arch Surg* 1989;124:681-683)

Percutaneous fine-needle biopsy is a technique that has become useful in the diagnosis of pancreatic malignant neoplasia. It can enable the surgeon to obtain a positive diagnosis of malignant neoplasm before laparotomy, enabling her or him to better plan her or his operative procedure and often to shorten her or his operating time. It can also help to avoid laparotomy in those patients who are not good candidates for surgery because of their age or poor health, and in those who have unresectable disease but do not have either biliary tract or gastrointestinal obstruction and are candidates for nonsurgical palliation.

In addition, fine-needle biopsy has been utilized at the time of laparotomy to biopsy pancreatic masses under direct vision to obtain an immediate diagnosis on the basis of microscopic tissue examination. It is believed to be safer and less likely to result in complications when compared with shave, wedge, or large-bore needle biopsies. This study was undertaken to determine the accuracy of this technique and its sensitivity and specificity when done both percutaneously in the radiology suite and under direct vision in the operating room.

MATERIALS AND METHODS

From 1978 to 1987 inclusive, percutaneous fine-needle biopsies of the pancreas were performed on 87 patients in Presbyterian and St Joseph Hospitals, Albuquerque. Fifty-five of these were done in the radiology departments and 32 were done at laparotomy in the operating room.

Smears prepared from tissue aspirated in gauge 20-22 needles at the time of the procedure were immediately fixed in 95% alcohol. For rapid diagnosis of aspirations performed during surgery, representative smears were stained with hematoxylin-eosin with standard procedure used for staining frozen section slides. The remaining smears were stained with the Papanicolaou stain. In addition, following smear preparation, the aspiration needle and syringe were washed out with 95% alcohol; a cell block was prepared from the tissue fragments in the alcohol. Step sections of the cell block were prepared and stained with hematoxylin-eosin. Percutaneous needle biopsies were done with the aid of computed tomography on GE 8800 and GE 8900 scanners.

The accuracy of cytological diagnoses from fine-needle aspirations was determined whenever possible by examination of patients' medical records to see the results of subsequent microscopic tissue examination at surgical procedures or postmortem examinations. Where this was not available, a clinical course that was progressively downhill and resulted in death within two years was considered a presumptive confirmation of positive cytology. Of patients in this latter category, only one survived longer than 18 months. A course of continuing good health or symptoms compatible with chronic pancreatitis were considered confirmation of cytological examination negative for malignant neoplasm. Patients who had negative cytological examinations and who did not have surgery done, but had a course compatible with benign disease, were all followed up for at least 18 months. None of the patients who had percutaneous aspiration biopsies had aspiration biopsies subsequently at operation, although 14 of these had wedge or shave biopsies.

Sensitivity is defined as true-positives minus (true-positives plus false-negatives) and specificity as true-negatives minus (true-negatives plus false-positives). Predictive value (accuracy) for a positive test is defined as true-positives minus (true-positives plus false-positives) and for a negative test, true-negatives minus (true-negatives plus false-negatives).

RESULTS

Of the 55 percutaneous fine-needle biopsies performed in the radiology suite, 47 had an adequate follow-up. This forms our determinate group. Of these 47 patients (Table), biopsies of 17 were unequivocally positive for carcinoma, five were reported as showing "suspicious" or "atypical cells," and 25 were negative for carcinoma. Of the 17 patients who had unequivocally positive aspirations (Ta-

*Immunoblastic sarcoma.

ble), three had tissue confirmation by surgical specimens removed at operative procedures and 14 had a course compatible with pancreatic carcinoma. Of the five patients who had suspicious or atypical cells, two were confirmed at subsequent surgical procedures as having pancreatic carcinoma, and three died within six months following aspiration with a course compatible with pancreatic carcinoma. There were no false-positives. There were 13 patients with negative cytological examinations for carcinoma who were subsequently found to have pancreatic carcinoma on the basis of tissue removed at surgery or at autopsy, or on the basis of their clinical course. The predictive value of a positive test was 100% in the 17 patients with unequivocally positive biopsy.

Of the 47 patients with adequate follow-up, 19 patients had biopsies that showed normal pancreatic tissue (unequivocally negative); two biopsies were reported as showing "liver cells," one as "pancreatitis," one as "fat necrosis," one as "unsatisfactory," and one as "atypical mucinous epithelial cells that do not appear to be pancreas" (Table). Twelve patients were confirmed as not having pancreatic carcinoma by either subsequent operations or a benign course of more than 18 months. There were 13 false-negative aspirations; nine patients were found at operation or autopsy to have histologically documented pancreatic carcinoma, and four had a course compatible with pancreatic carcinoma, dying in less than 18 months. The patient reported as having pancreatitis was one of those subsequently found to have pancreatic carcinoma at surgery, and three of the patients who had cells other than pancreas aspirated had a course compatible with pancreatic carcinoma. The predictive value of a negative test was 48%. Considering only unequivocal tests as positive, the sensitivity of the percutaneous biopsy was 57%. The specificity was 100%.

Thirty-two fine-needle aspirations were done under direct vision in the operating room, of which 30 had an adequate follow-up (Table). Thirteen of these were reported as unequivocally positive, three as suspicious or atypical cells, and 14 as negative. In the unequivocally positive group, three were confirmed by histological examination of the surgical specimen removed at operation, and ten patients died in less than 18 months with a course compatible with pancreatic carcinoma (Table). In the patients with suspicious and atypical cells, two had a course compatible with pancreatic carcinoma ending in death, and one was found to have immunoblastic sarcoma on the basis of a surgical specimen consisting of a bowel segment and fatty tissue. There were no false-positives, so in this setting the predictive value of a positive test was also 100%.

Nine of the 14 fine-needle biopsies negative for carcinoma were confirmed as true-negatives; three were confirmed by histological examination of resected surgical specimens, and six patients had a benign course and are alive and well after 18 months or more (Table). There were five false-negative aspirations. Two of the false-negatives were confirmed as adenocarcinomas of the pancreas by Whipple procedures, one by positive cytological examination that was rendered the day following surgery (therefore not available to the surgeon at the time of the initial operation), one at a second operation, and one by a course compatible with pancreatic malignant neoplasm. Considering only those tests where pancreatic tissue was obtained and was negative for carcinoma, the predictive value of a negative test was 62%. The sensitivity of the operating room biopsy was 72%; specificity was 100%.

Of all the 47 patients in the percutaneous aspiration group, 35 had pancreatic carcinoma; 17 (49%) of these were diagnosed by the procedure, and 18 (51%) were not. Of the latter 18, five were in the group with suspicious or atypical cells, and all five were subsequently determined to have pancreatic carcinoma. In 13 the diagnosis was not made, presumably because of failure to get the needle in the tumor or obtaining an inadequate or poorly prepared specimen. In the group of 30 patients with open biopsies performed at surgery with adequate follow-up, 20 had pancreatic carcinoma; 13 (65%) of these were identified by needle aspiration and seven (35%) were not. Of the seven patients who were not correctly diagnosed, two were reported equivocally as having suspicious or atypical cells, and five were false-negatives. As anticipated, there was increased accuracy at the operating table (65% vs 49%)

due to a decrease in false-negative aspirations; for these values, $P = .32$, which is not significant and is related to the small size of the sample.

COMMENT

We believe that fine-needle aspiration biopsy of the pancreas is a helpful modality in diagnosing pancreatic carcinoma. When positive, it can be relied on when the cytological examination is done by an experienced pathologist.

Pathologists do not give a positive diagnosis of pancreatic malignant neoplasm on fine-needle aspiration cytology unless they are very sure. False-negative cytology reports and reports of suspicious cells will continue to be presented to surgeons due to failure of the needle to hit the tumor mass or due to hitting areas of necrotic tissue or surrounding pancreatitis. In addition, the presence of well-differentiated carcinoma, where individual tumor cells show little or no cellular atypia, will always be a problem. Some improvement may be expected as additional skill in doing and interpreting this procedure is gained, but this improvement will be small, since our findings are essentially the same as the findings of those who have had the opportunity to look at a large amount of clinical material.

Holm et al[1] reported a 9.8% predictive accuracy on percutaneous fine-needle aspiration of malignant pancreatic lesions. Their two false-positives were due to initial cytological misinterpretations, which were later revised. For nonmalignant lesions, their predictive accuracy was 70%. Dickey et al[2] reported an overall accuracy of 97.3% with one false-negative and no false-positive results; their sensitivity was 71.9%. Others have reported a specificity of 100%.[3-6] No complications were reported in our series in either the percutaneous or open biopsies. There was no evidence in any of the percutaneous studies of seeding of the tumor, although this has been reported,[7] as has pancreatitis[8] following percutaneous pancreatic aspiration.

We are grateful to Julia Lujan, CTR, Presbyterian Hospital Tumor Registrar, and Dolores Moya, St Joseph Hospital Tumor Registrar, for their assistance in this study.

Serum Cholesterol and 25-Year Incidence of and Mortality From Myocardial Infarction and Cancer: The Zutphen Study

Daan Kromhout, PhD, MPH; Edward B. Bosschieter, MD; Marjon Drijver, MD, RD; Cor de Lezenne Coulander, MSc

In the Zutphen Study, cholesterol determinations were carried out in 1960 in serum of 829 middle-aged men. Between 1960 and 1985, detailed information was collected on morbidity and mortality in these men. During 25 years of follow-up, 179 men developed myocardial infarctions and 203 developed cancer. During this period, 110 men died of myocardial infarction, 144 of cancer, and 410 of all causes. Survival analysis showed that the serum cholesterol level in 1960 was independently related to the 25-year incidence of myocardial infarction. This long-term relation was mainly due to the strong association between serum cholesterol level and 15-year incidence of myocardial infarction. Similar but less pronounced relations were found between serum cholesterol level and 15- and 25-year mortality from myocardial infarction. Serum cholesterol level was related neither to long-term incidence of and mortality from cancer nor to mortality from all causes (*Arch Intern Med* 1988;148:1051-1055).

Colorectal Neodymium-YAG Photoablative Therapy

Comparing Applications and Complications on Both Sides of the Peritoneal Reflection

Donald E. Low, MD; Richard A. Kozarek, MD; Terrence J. Ball, MD; David J. Patterson, MD; Lucius D. Hill, MD

• Laser photoablative therapy has seen wide application in the esophagus, stomach, and rectum. Its use in the supraperitoneal colon has been less extensive because of fear of complications. One hundred fifteen patients who presented during a four-year period and underwent neodymium-YAG laser treatment on both sides of the peritoneal reflection (rectum, 47 patients; colon, 68 patients) were reviewed. The various lesions treated with laser therapy included 32 malignant tumors that presented with bleeding or obstruction, 44 large broad-based villous adenomas, six carcinoid tumors, and 33 patients with arteriovenous malformations or radiation proctitis who presented with acute hemorrhage or chronic blood loss. Overall treatment efficiency was 83% in the rectal group vs 87% in the colonic group. There was no significant difference in complication frequency or severity between the two groups, even though 45% of the colonic lesions were located in the thin-walled cecum. There was no laser-related mortality in this series. Laser photoablative therapy is safe and effective treatment for a wide variety of colorectal lesions. In experienced hands, it can be used on either side of the peritoneal reflection with equal efficiency and no increased risk of complications.

(*Arch Surg* 1989;124:684-688)

Laser photoablative therapy has seen increasing utilization throughout the gastrointestinal tract within the last decade. Its application in treating malignant and benign neoplasms of the esophagus,[1-3] stomach,[4] and colorectum,[5-9] as well as various forms of intestinal hemorrhage,[10-12] has been well documented. Despite the increasing level of experience, there continues to be a general reticence to treat colonic lesions above the peritoneal reflection because of concern regarding severity and frequency of potential complications.

The intraperitoneal colon and especially the cecum do not allow the margin for error that exists when treating rectal lesions. Intestinal perforation can result in general abdominal contamination and peritonitis with an expected high mortality rate. This is especially true, considering that many of the patients who are thought to be best suited for laser treatment are older individuals; often, they have concomitant medical problems. Although an increased risk is generally accepted, we are not aware of any reports that have examined whether this risk translates into actual increased morbidity and mortality. This study analyzes and compares a large experience with laser treatment both above and below the peritoneal reflection.

Accepted for publication Sept 30, 1988.

PATIENTS AND METHODS

All patients referred to the Virginia Mason Medical Center, Seattle, for laser photoablative therapy of colorectal lesions were reviewed. Patients who were not obstructed or who were not hemorrhaging acutely underwent a full bowel preparation with magnesium citrate, bisacodyl (Dulcolax) tablets, and phospho-soda (Fleet) enemas. Intravenous meperidine hydrochloride or diazepam sedation was individualized for each patient, and whenever possible, a total colonoscopic examination was carried out to rule out the presence of synchronous colonic lesions. General anesthesia was never required, and cases were done as outpatient procedures whenever possible. Prophylactic intravenous antibiotics were used in all patients with indwelling prostheses or a history of bacterial endocarditis.

Endoscopic examination was carried out with either a colonoscope (Olympus CF-1T-10L) or a flexible sigmoidoscope (CFP-105). We used a neodymium (Nd)-YAG high-powered laser (Cooper model 8000) with an energy delivery capability between 1 and 100 W. A flexible quartz laser fiber was introduced through the biopsy port of the endoscope, and treatment was aided by a visible aiming light that parallels the size and position of the laser treatment beam. We have used a bare fiber without coaxial air or carbon dioxide infusion and varied the power setting according to the lesion being treated and whether a hemostatic or photoablative effect was desired.

Treatment of Neoplasms

Treatment of villous adenomas, malignant tumors, and carcinoids was initiated with a patient in the left lateral decubitus position although other positions were frequently used to improve access in lesions that were difficult to visualize initially. Lesions that included a major intraluminal component were initially débrided by utilizing either a piecemeal snare resection or the "artificial sapphire" contact tip laser probe. The crystal contact tips provide a selection of various dissecting probes that are connected to the tip of the laser fiber and deliver energy to tissues through actual contact. This delivery system can work at lower power settings and does not produce the same depth of tissue damage as the external-beam laser. The shape and configuration of these crystals can be changed, depending on whether a hemostatic, vaporization, or dissection effect is required.

Piecemeal snare débridement was used whenever possible before laser therapy to decrease the intraluminal mass of tissue that required treatment. Villous adenomas can usually be resected

down to the level of the broad-based stalk, while malignant tumors can be débrided to enlarge the residual colonic lumen to facilitate examination and treatment of the entire lesion. Snare débridement can also produce large volumes of tissue for histologic analysis; this is particularly important in the treatment of large villous adenomas. The discovery of an invasive malignant neoplasm within a colonic adenoma should always result in surgical excision and proper staging. Tissue samples of villous adenomas are obtained for pathologic analysis at the time of initial treatment, before repeated treatments, and during additional treatments carried out on recurrent lesions. However, treatment is not delayed to obtain the pathologic findings, because laser therapy does not interfere with subsequent surgical resection should it be required. In this series, all patients with malignant polyps were sent for surgical resection, with the exception of two patients who were not considered candidates for surgery because of coexistent medical disabilities.

Villous adenomas and carcinoids were treated in a circumferential fashion, beginning at their outside border and progressing inward. Malignant tumors were treated from the proximal to distal extent following snare débridement; this may have involved identifying the lumen with a flexible wire before passing the pediatric colonoscope or beginning snare resection. Neoplastic lesions were treated with energy settings of 50 to 80 W with a pulse duration of 0.5 to 1 s. Following initial treatment sessions, patients with large villous adenomas or malignant tumors were re-treated at two to four days, then every three to four weeks until complete photoablation or adequate palliation had been achieved. For benign lesions, additional follow-up was done every six months for one year, then annually. Patients who presented with extensive obstructing tumors were treated according to the rapidity of their symptom recurrence.

The laser treatment effect resulted from thermal damage, and the length of individual treatments in each patient was modified according to the visualized tissue effect. We utilized a constant-suctioning apparatus that continually evacuated smoke through the biopsy port during treatment. Clear visibility was essential to ensure that excessive cavitation did not result in perforation. Cavitation occurs when tissue is vaporized deeply into the lesion and potentially into the bowel wall. Smoke evacuation is especially important when treating lesions in the thin-walled cecum where the potential for perforation is increased.

Treatment of Arteriovenous Malformations (AVMs) and Radiation Proctitis

Patients who were selected for laser therapy for AVMs had a history of acute gastrointestinal hemorrhage or chronic blood loss. Those patients with AVMs all had their vascular lesions previously documented, either endoscopically or with arteriography. They also had upper tract endoscopy to rule out the presence of additional AVMs proximal to the ligament of Treitz.

These lesions were treated in a circumferential fashion with pulses of 0.1 to 0.5 s at an energy setting of 30 to 50 W. Treatments were not routinely repeated unless there was persistent evidence of ongoing blood loss. Radiation proctitis was treated at similar energy settings, but treatment was usually required over a larger area for treating multiple individual telangiectasias.

Treatment was deemed to be successful in the various groups when, after a minimum of two months of follow-up, (1) patients with malignant tumors had no problems with hemorrhage or obstruction and required no surgical intervention, (2) patients with villous adenomas or carcinoids demonstrated complete photoablation, and (3) patients with AVMs and radiation proctitis demonstrated no evidence of persistent or recurrent hemorrhage.

RESULTS

The charts of 115 patients who underwent colorectal Nd-YAG laser therapy in the four-year period between October 1983 and October 1987 were reviewed. This group included 53 males and 62 females, with a mean age of 70.1 years (age range, 25 to 90 years).

Laser was considered to be definitive therapy in approximately half of the patients, whereas in the other half, it was utilized because of poor operative risk, surgery refusal, or disease extent (Table 1). The type of lesions treated and their relative location to the peritoneal reflection are shown

in Tables 2 and 3. Forty-seven patients had lesions located in the rectum, while 68 patients had a colonic pathologic condition. Lesions were considered to be in the "extraperitoneal rectum" if they were located within 15 cm of the anal verge. Reasons for laser therapy included hemorrhage from AVMs (n = 31), radiation proctitis (n = 2), and various types of neoplasms, ie, villous adenomas (n = 44), carcinoids (n = 6), and malignant tumors (n = 32). Presentation was variable, with some patients demonstrating rectal hemorrhage (n = 43), colonic obstruction (n = 15), or both (n = 11). Forty-six patients presented for nonsurgical definitive treatment of colorectal neoplasms. Villous adenomas were treated if they were broad based and removal with snare cautery alone would be unsafe or incomplete. Polyp size ranged from 1 to 6 cm, with 75% being larger than 3 cm^2. Patients with bleeding or obstructing neoplasms were treated only when surgery was refused or contraindicated. Patients with acute or chronic gastrointestinal hemorrhage and documented colorectal AVMs were treated after upper gastrointestinal tract endoscopy had been done to rule out coexistent AVMs proximal to the ligament of Treitz.

Abdominal pain was the most common presenting complaint (n = 14), followed by nausea (n = 7), diarrhea (n = 7), vomiting (n = 2), and mucous discharge (n = 2). Thirty-seven patients (13 rectum and 24 colon conditions) presented with bleeding that required intermittent transfusions, and 11 patients had undergone previous colonic resections (six with cancer, two with AVMs, two with familial polyposis, and one with chronic ulcerative colitis). A total of seven patients (one rectum and six colon conditions) had coagulation abnormalities, including either chronic anticoagulation (n = 5), von Willebrand's disease (n = 1), or idiopathic thrombocytopenic purpura (n = 1).

The treatment frequency and energy delivery to lesions in the colon and rectum are compared in Table 4, and the treatment results for malignant and benign lesions are reported in Table 5. The overall treatment success rate was 83% in rectal lesions (mean follow-up, 11 months) vs 87% in colonic lesions (mean follow-up, 15 months).

Neoplasms

In lesions that were treated for complete photoablation (44 villous adenomas and six rectal carcinoids), 43 had a complete response, with two additional patients with villous adenomas undergoing continued treatment and one patient unavailable for follow-up (Table 6). Recurrence following photoablation of villous adenomas occurred in four patients (10%) during follow-up; however, in every instance, the recurrence was controlled with one additional laser treatment. Ongoing treatment has continued in three patients with bleeding and obstructing cancers (one colon and two rectum conditions) and in one patient with an obstructing colonic cancer. These patients were at very high surgical risk, but they have been successfully palliated with laser treatment for 15, 15, 24, and 28 months, respectively. Treatment failures were seen in seven patients with cancer (rectal [n = 6] and colonic [n = 1]) who ultimately required either a colostomy or resection (n = 5) or who had ongoing low-grade blood loss despite treatment (n = 2).

Table 6.—Overall Treatment Success Related to Type of Lesion Undergoing Nd-YAG Laser Treatment*

	Total No.	Mean Follow-up, mo	Treatment Success No. (%)	Definition
Cancer	32	10.3	25 (78)	Effective palliation of bleeding and obstruction or photoablation of malignant polyps (n = 2)
AVMs	31	16.5	26 (81)	No further evidence of hemorrhage or chronic blood loss
Radiation proctitis	2	8.5	1 (50)	No further evidence of hemorrhage or chronic blood loss
Villous adenomas	44	23.4	37 (84)	Complete photoablation
Carcinoids	6	13	6 (100)	Complete photoablation
Total	**115**	. . .	. . .	. . .

*AVMs indicates arteriovenous malformations; Nd, neodymium.

AVMs and Radiation Proctitis

Failures also occurred in six patients with colonic AVMs who required resection or had persistent evidence of chronic blood loss and in one patient with radiation proctitis who had persistent blood loss and required a colostomy for incontinence. Overall results of colorectal lesions treated with laser therapy, stratified according to the type of lesion under treatment, is shown in Table 6.

Complications

A total of 233 laser treatments were carried out with 178 (80%) done on an outpatient basis. There was no laser-

Table 7.—Complications Following Laser Therapy

related mortality, and overall complications in rectal and colonic lesions are compared in Table 7. Delayed hemorrhage was the most common complication, occurring in three patients in both groups. Stenosis occurred in three patients (rectum [n=2] and colon [n=1]) but was never clinically significant. The perforation in the colonic group occurred in a patient who was being treated for chronic bleeding secondary to a right colonic AVM. The perforation actually occurred in the ileum when it was examined during colonoscopy and an additional AVM was treated at that time. A colocutaneous fistula occurred in one patient who was transferred to our institution after having three previous colorectal resections for malignant neoplasms during the previous 16 years; she had a completely obstructing tumor of her residual transverse colon, a significant component of which was secondary to extrinsic compression. She was a borderline candidate for surgical treatment due to severe cardiorespiratory disease and was therefore given six laser treatments via her colostomy during the following two years to maintain a patent colonic lumen. She developed a colocutaneous fistula two months after her last laser treatment and ultimately required a defunctioning ileostomy.

COMMENT

The Nd-YAG laser is an effective treatment modality in a variety of bleeding and neoplastic conditions within the gastrointestinal tract. The majority of reports on lower intestinal tract applications have examined predominantly rectal lesions.[5,13-16] The Nd-YAG laser utilizes a near-infrared wavelength of 1.06 μm with a potential penetration depth of 4 mm. The laser energy is only partially absorbed by water and hemoglobin, and it can therefore penetrate deeply into tissue to vaporize tissue or coagulate actively bleeding vessels. The penetrating power of the Nd-YAG laser is four times greater than the argon laser and 40 times greater than the carbon dioxide laser. It is this increased power delivery that not only makes it an effective therapeutic tool but increases the chance of perforation in inexperienced hands. The current applications of Nd-YAG laser technology in the colorectum include treatment of sites of colonic hemorrhage and benign neoplasms and nonsurgical palliation of malignant tumors.

Neoplasms

Fully 7% of all rectal and distal sigmoid tumors are not suitable for surgical resection on the basis of medical disabilities or extent of disease.[17] In addition, mortality rates of up to 22% have been reported in operations on obstructed rectal tumors before decompression.[18] Laser treatment provides excellent palliation in nonresectable

Table 8.—Location of Colonic Lesions*

	No.

†Five patients with AVMs had lesions in more than one region of the colon.

rectal tumors[14,15,19] and improves morbidity and mortality figures by avoiding two- and three-stage procedures in patients who present with obstructing malignant lesions of the rectosigmoid.[7,20]

Historical management of these tumors has included electrocoagulation, cryotherapy, and external radiation. We believe that laser therapy provides significant advantages over all these treatments. Electrocoagulation usually requires a general anesthetic, cannot be applied proximal to the peritoneal reflection, and has been associated with high complication rates.[21] Cryotherapy is effective, but it is associated with weeks of posttreatment rectal discharge and has a significant propensity for delayed hemorrhage.[22,23] External radiation is effective on smaller lesions but less so with extensive rectal tumors[24,25] and is associated with an increased incidence of side effects and complications.[26]

Broad-based villous adenomas have traditionally been managed surgically, either via a colotomy or with a transanal or segmental surgical resection. There is, as yet, no good evidence that malignant polyps should be treated with any modality other than surgical resection. Virtually all patients with villous adenomas at our institution undergo extensive snare débridement before laser treatment, which provides significant volumes of neoplastic tissue for histologic analysis. This is an important step that will help rule out the presence of malignancy in these large polyps and ultimately decrease the number of treatments necessary for complete photoablation. The chance of finding an invasive malignant focus is greater as the polyp size increases,[27-29] and the incidence of missing a malignant neoplasm with visual inspection alone is approximately 10%[30]

AVMs

The treatment of colonic AVMs with laser therapy is more controversial, although reports have shown that effective treatment can be achieved in up to 82% of patients with 24 months of follow-up.[12] These are good results when compared with recurrence rates as high as 10% in patients with AVMs who undergo surgical resection.[31] Although the treatment of individual AVMs requires fewer treatments and less overall energy delivery, the risk of perforation when treating these lesions is actually higher than in neoplastic lesions. The AVMs occur in the submucosa and can involve the mucosa or muscularis of an otherwise normal, unaltered colonic wall. Endoscopic management, whether laser, heater probe, sclerotherapy, or monopolar biopsy forceps involves treatment without the increased safety associated with chronic inflammation or neoplastic growth. Therefore, when carrying out a single treatment of an isolated AVM by applying 200 to 600 J, it would seem safer in relative terms when compared with delivering many thousands of joules in multiple treatments to a rectal malignant neoplasm. However, in actual fact, it is quite the contrary.

Energy delivery, as reported in all laser studies, can be very misleading. The actual tissue effect produced by laser treatment is as much an expression of the operator's skill and technique as it is the actual laser power settings. Bursts of laser energy delivered at greater than 1.5 cm from the lesion will have relatively little tissue effect regardless of the power setting. The absence of a correlation among the total energy level, duration of treatment, and complication rates has been noted previously.[32] Treatment duration and timing must be gauged on the basis of visualized tissue effect alone. Laser endoscopists can vary power settings to enhance a hemostatic or vaporizing effect, but most importantly, they must be able to recognize and avoid excessive cavitation.

Initial examination of Table 4 would indicate that a lower energy delivery in fewer treatment sessions might explain the absence of more serious colonic complications. However, the lesions treated within the colon were more likely to be AVMs (48%), and lesions were most often treated in the thin-walled cecum (45%) (Table 8). As a result, the lower energy delivery is a simple expression of adapting treatment to the individual lesion and its location. This is particularly true when overall treatment efficiency is virtually identical (rectum, 83%; colon, 87%).

Even though 33 individual lesions were treated in the cecum, no serious complications occurred in this high-risk area. Overall, there was no statistically significant difference between treatment success or incidence of major complications between the rectal and colonic groups. Major complications, ie, delayed hemorrhage, stenosis, and perforation, occurred in five rectal patients and six colonic patients.

The colocutaneous fistula and two treatment failures in patients with rectal cancers occurred in situations that included significant extrinsic compression at initial presentation. We believe that patients with obstruction due to extrinsic compression respond poorly to laser treatment and may be more vulnerable to laser-induced complications. The incidence of delayed hemorrhage was the same in rectal (n=3) and colonic (n=3) lesions although the colonic group contained a higher percentage of patients with major coagulation abnormalities, such as chronic anticoagulation, von Willebrand's, or idiopathic thrombocytopenic purpura. A bleeding abnormality likely contributed to one treatment failure in a patient with a right colonic AVM, but this was not a factor in any patient with delayed hemorrhage. Taken as a total group, the incidence of major complications was 10%, which compares favorably with other large laser series.[33]

CONCLUSION

In this group of 115 patients, 47 of whom had a rectal lesions and 68 of whom had a colonic lesion, we could find no significant difference in overall treatment efficiency or incidence of major complications between the two groups. We would emphasize, however, that there was a significant learning curve in utilizing the Nd-YAG laser endoscopically. It is important therefore that all potential laser endoscopists learn the visual cues associated with laser effect and cavitation before applying this modality to lesions above the peritoneal reflection.

Small-Bowel Perforation Complicating the Open Treatment of Generalized Peritonitis

Walter J. B. Mastboom, MD; Han H. C. Kuypers, MD, PhD; Frans J. Schoots, MD; Theo Wobbes, MD, PhD

• Fourteen patients were found to have developed 53 small-bowel perforations in the absence of pathogenic factors during "open abdominal treatment" for generalized peritonitis. They occurred after three to 17 laparotomies, on average at the eighth postoperative day (one to 120 days). Forty-nine lesions were located superficially. A relation with organ system failure, routine blood tests, type of nutrition, or microorganisms could not be demonstrated. The etiology of the lesions remains uncertain, but the open abdominal treatment must play some important role in its pathophysiology. Five patients survived. The therapy of choice appears to be mobilization of the bowel with resection of the affected part and primary anastomosis.

(*Arch Surg* 1989;124:689-692)

The occurrence of nontraumatic small-bowel perforations is rare. Several pathophysiological factors are known, such as vascular disorders, infectious diseases such as tuberculosis and typhus, Crohn's disease, disseminated malignant disease, medication with potassium tablets or corticosteroids, and radiotherapy.[1-6] In some cases the cause is unknown or uncertain, and such cases are classified as "spontaneous."

We have noticed the occurrence of small-bowel perforations during "open treatment" of patients with intra-abdominal sepsis when factors predisposing to intestinal perforations were absent. This group of patients has been studied in an attempt to establish under which circumstances these perforations occurred, what the cause might have been, and how they should be treated.

PATIENTS AND METHODS

Open Treatment of Intra-abdominal Sepsis

In patients who remain septic during the treatment of generalized peritonitis, we perform relaparotomy when extra-abdominal causes for sepsis have been excluded.[7] During this operation, the whole bowel is mobilized to detect and drain all abscesses. Frequently, persisting sepsis necessitates multiple laparotomies. Sometimes primary closure of the abdominal wall is impossible without extreme tension on the fascial sutures. To avoid complications caused by fascial disruption, the abdominal wall is then left open and a nylon mesh is sutured to the wound edges to prevent intestinal eventration.[8] Occasionally the bowel is so stiff, due to fibrosis and edema, that protrusion through the abdominal wound is unlikely to occur and application of a mesh is omitted.

When reexploration is indicated within a few days, the mesh can easily be removed since it is not attached yet to the underlying bowel loops. However, with time, exploration of the abdominal cavity becomes more difficult. Progressive formation of fibrous granulation tissue overgrowing the abdominal wound complicates removal of the mesh, and complete mobilization of the bowel loops is hindered by diffuse adhesions. Consequently, extensive exploration of the peritoneal cavity performed in these patients might be complicated by iatrogenic bowel perforations. Usually, these lesions are detected during the surgical procedure. So as not to miss undetected lesions, the whole bowel is always checked before terminating the operation. Serosal lesions occur frequently under these circumstances. Extensive serosal avulsions, sometimes including more than half the bowel circumference, are closed in one layer as much as possible, whereas small lesions are considered unimportant and left undisturbed. As a result of the complicated course of their intra-abdominal sepsis, most patients with an "open abdomen" need intensive care unit (ICU) treatment.

Gauzes drenched in isotonic saline solution (0.9% sodium chloride) are applied and changed at least twice a day to prevent both sticking to the wound and dehydration. Thus, leakage from a bowel perforation is detected within hours. Superficial intestinal lesions can be seen as mucosal blowouts producing bowel fluids; deeper lesions are only detected during surgery. Bowel perforations detected within 24 hours after laparotomy were considered to occur from unnoticed iatrogenic lesions.

When reexploration is no longer necessary, the granulating layer becomes thicker and contracts. Epithelialization from the wound edges occurs, and mesh grafts may be applied.

Between July 1977 and July 1987, 394 patients were treated for generalized peritonitis in the Department of General Surgery at University Hospital Nijmegen, Nijmegen, the Netherlands. During the course of the disease, the abdominal wall was left open in 135 patients, and a mesh was applied for some period in all. Twenty-seven patients developed perforations in the jejunum or ileum. After exclusion of factors predisposing to small-bowel perforations, as already mentioned, 14 patients remained for analysis. The records were reviewed only when perforations had appeared more than 24 hours after laparotomy and no suture material was found at or near the site of the lesion.

To detect factors that might have contributed to the occurrence of small-bowel perforations, several factors were examined. Multiple perforations diagnosed at the same time were considered as one event for further analysis. Medical history, primary cause of the intra-abdominal sepsis, and duration of ICU treatment were examined for each patient.

Several variables were analyzed at the time of each perforation, including individual functions of seven organ systems, which were scored according to the Multiple Organ Failure (MOF) Scale modified by Goris et al[9] (Table 1), the presence of a mesh, type of nutrition, and cultures taken from intra-abdominal foci during laparotomy. Other variables were only studied when they were determined within 24 hours before occurrence of the lesions, such as hemoglobin concentration, serum albumin and protein concentrations, and blood cultures.

RESULTS

Small-bowel perforations occurred in five women and nine men during open treatment for intra-abdominal sepsis (Table 2). Their mean age was 51 years (ranging from 19 to 79 years). Primary causes of the generalized peritonitis were necrotizing hemorrhagic pancreatitis (six patients), anastomotic dehiscence (three), septic aortoiliac graft (two), septic cholangitis (one), diverticulitis (one), and colonic perforation (one).

All underwent several laparotomies, varying from four to 20 times. Overall, 20 iatrogenic perforations occurred during these procedures.

Altogether, 53 noniatrogenic perforations were found. Several perforations were diagnosed simultaneously on ten occasions; six times there were two and twice there were three lesions. Thus, the diagnosis of small-bowel perfora-

Accepted for publication Nov 16, 1988.

tion of unknown origin was made 43 times, varying from one to 13 times per patient. The perforations occurred after the third to 17th laparotomy, varying from the first to the 120th postoperative day (mean, day 8; Figure). In ten patients, the diagnosis was made several times. The intervening periods varied from one to 88 days. Forty-nine lesions were located superficially, whereas four deep lesions were found at laparotomy. Nine perforations (17%) were observed while a mesh was absent. All 14 patients needed ICU treatment for their intraabdominal sepsis; admittance to the ICU varied from one to six times. Total length of stay ranged from three to 275 days (mean, 74 days). Twenty-two times (51%) the diagnosis of small-bowel perforation was made on this ward.

Table 3 shows that respiratory insufficiency was present during diagnosis of 37% of the perforations. Concerning the digestive tract, hepatic failure was present ten times (23%) and stress ulcer was present on one occasion. Forty-four percent of the small-bowel perforations were diagnosed in the absence of serious insufficiency of the organs checked, according to Table 1, but eight times the MOF score was 4 or more, indicating serious disturbances of several organ systems.

MOF Score	No. (%) of Perforations
0	19 (44)
1	3 (7)
2	4 (9)
3	9 (21)
4	4 (9)
5	3 (7)
6	0 (0)
7	0 (0)
8	1 (2)

Five times (12%) perforations were detected while the patient was anemic (hemoglobin level, <95 g/L; normal, 120 to 180 g/L).

Hemoglobin Level, g/L	No. of Perforations
<80	2
80-95	3
95-110	15
≥110	17
Not measured	6

Hypoalbuminemia and hypoproteinemia were often present; severe deficiencies were present, respectively, in 18% (serum albumin concentration, ≤20 g/L; normal, 35 to 50 g/L) and 9% (serum total protein concentration, ≤44 g/L; normal, 65 to 80 g/L) of the times measured.

Level, g/L	No. of Perforations
Albumin

Most lesions were diagnosed when patients were parenterally fed. Sixteen times they received enteral nutrition, seven times in combination with parenteral support.

Type of Nourishment	No. of Perforations
Probe feeding or normal diet	9
Parenteral nutrition	25
Combination	7
No feeding	2

Table 1.—Scoring of Multiple Organ Failure*

Organ System	Score	Variable
Respiratory	0	No mechanical ventilation
	1	PEEP ≤10 cm H_2O and F_{IO_2} ≤0.4
	2	PEEP >10 cm H_2O and/or F_{IO_2} >0.4
Cardiovascular	0	Normal blood pressure without vasoactive substances
	1	Blood pressure >100 mm Hg by volume loading; dopamine hydrochloride ≤10 μg/kg/min or nitroglycerin ≤20 μg/kg/min
	2	Blood pressure ≤100 mm Hg and/or dopamine hydrochloride >10 μg/kg/min and/or nitroglycerin >20 μg/kg/min
Renal	0	Serum creatinine <177 μmol/L
	1	Serum creatinine ≥177 μmol/L
	2	Hemodialysis or peritoneal dialysis necessary
Hepatic	0	AST <25 U/L and total bilirubin <30 μmol/L
	1	Total bilirubin 30-89 μmol/L or AST 25-49 U/L
	2	Total bilirubin ≥90 μmol/L or AST ≥50 U/L
Hematological	0	Normal counts of thrombocytes and leukocytes
	1	Thrombocytopenia $<50 \times 10^9$/L and/or leukocytes $0.03\text{-}0.059 \times 10^9$/L
	2	Hemorrhagic diathesis or leukocytes $<0.0025 \times 10^9$/L or leukocytes $\geq 0.06 \times 10^9$/L
Gastrointestinal	0	. . .
	1	Acalculous cholecystitis or stress ulcer
	2	Bleeding from stress ulcer necessitating >2 U/24 h blood, necrotizing enterocolitis and/or pancreatitis, and/or spontaneous perforation of gallbladder
Neurological	0	Normal functioning
	1	Clearly diminished responsiveness
	2	Severely disturbed responsiveness and/or diffuse neuropathy

*PEEP indicates positive end-expiratory pressure; F_{IO_2}, fraction of inspired oxygen; and AST, aspartate aminotransferase.

Microorganisms cultured from blood samples and abdominal foci are detailed in Table 4. A wide variety of microorganisms was cultured showing no relation with the occurrence of the intestinal perforations.

Forty-six of the 53 perforations were treated surgically. Twenty-nine laparotomies were performed for 41 lesions. Twenty-two perforations were closed in layers, with a secondary dehiscense in four. Thirteen resections were performed for 19 lesions. A stoma was constructed in seven cases, whereas continuity was restored in six. Dehiscence was not observed. Five superficial lesions were directly closed in one layer without performing adhesiolysis or laparotomy. Dehiscence occurred in two.

Surgical treatment was rejected in four patients. They had already been treated previously for spontaneous small-bowel perforations, and new lesions occurred during the terminal stage of the intra-abdominal sepsis. Altogether, nine patients (64%) died, all due to the underlying diseases.

Four patients also developed colonic perforations without demonstrable cause. All these lesions were located superficially in the wound. Two of them occurred together with small-bowel perforations, the others on unrelated occasions. These colonic lesions were not analyzed in this study.

Table 2.—Clinical Data of 14 Patients With Small-Bowel Perforations*

*Blood samples taken within 24 hours before the occurrence of perforations (43 events); intra-abdominal contaminated pockets found during surgical treatment of the perforations. In blood samples, only solitary specimens of microorganisms were cultured. Once a single kind of microorganism was cultured from intra-abdominal foci (*S albus*); 13 times a mixture of two or more different microorganisms was cultured.

COMMENT

To our knowledge, the occurrence of intestinal perforations during open treatment for generalized peritonitis has not been described so far. We are aware that in our series some iatrogenic or mechanical factor cannot be denied. All perforations occurred after at least three preceding laparotomies for intra-abdominal sepsis, in which surgery is known to be technically difficult,[10] and only when the abdominal cavity had been left open. Thus, iatrogenic perforations and serosal lesions will inevitably occur. Since iatrogenic perforations are easily recognized during surgery, it is unlikely that they have been missed and have caused symptoms after a few days. Moreover, most perforations definitely would have been detected immediately postoperatively or during the first changing of the wound dressings, since 92.5% of the lesions were located in the exposed bowel surface, which was clearly visible at inspection.

Small serosal lesions, made during operation, were considered to be unimportant and not sutured. When, for some reason, relaparotomy was necessary after a few days, the mucosa on the spot was noted to bulge out and to be tense. It may be imagined that perforation would only be a matter of days, but it is our experience that this hardly ever happens. We believe this is due to the extrinsic counterpressure of the surrounding loops covering the lesions.

Even if serosal lacerations would be predisposing sites for perforations, this would only account for the early perforations, since the bowel loops in which late lesions occurred were covered with a thick, granulating, fibrotic plate. A mechanical factor as the only cause of the late perforations, ie, changing of a wound dressing sticking to the underlying layer, is rejected for the same reason. The nylon mesh applied to the wound edges seems to be a less important mechanical factor since 17% of the lesions had been diagnosed while a mesh was absent. All patients had been suffering from intra-abdominal sepsis and had been treated in the ICU for support of several organ systems; however, only 51% of the perforations were diagnosed on this ward. Nineteen (44%) of the 43 times, the patient was in a reasonable condition, as organ system failure was present in only 56%.

Although serious anemia, hypoalbuminemia, and hypoproteinemia did occur on some occasions, they were not clearly related to the lesions, as in most patients these deficiencies were absent or only moderate. It might be expected that ileus and parenteral feeding were predisposing factors, but 16 times the lesions occurred while the patient was enterally fed. No predisposing microorganisms have been cultured. Since no common causative factor could be found, we can only hypothesize about the pathophysiology of the perforations. In a few cases, we were able closely to follow the development of a superficial perforation several weeks after surgery. When the wound gauzes were changed, a small blisterlike elevation could be observed in the diffusely granulating surface. On palpation these felt like weak spots in a stiff, fibrotic plate. Within a few days they burst open. At first, small mucosal blowouts were seen, but within a few hours, while awaiting surgery, they became rather large defects, sometimes even mimicking a loop enterostomy. This demonstrates that traction forces are prevalent in the granulating wound. The abdominal wall, when left open, retracts sideways, enlarging the wound dehiscence, while the granulation tissue contracts in an effort to reduce it. Weak spots in the fibrotic plate may give way to these counteracting forces and cause bulging and rupture of the underlying bowel, which is stuck to it. The high recurrence rate (40%) of the lesions directly sutured without laparotomy supports this theory.

The occurrence of a spontaneous small-bowel perforation should not be considered as an indication that the patient is in the terminal phase of intra-abdominal sepsis. After all, 35% of the patients survived. Surgery, as difficult as it may be, should therefore not be rejected.

Mobilization of the bowel appears to be a sheer necessity. The granulating area is detached from the wound edges and split up, so that the prevalent traction forces are neutralized. When laparotomy was performed, there was a recurrence rate of 18% after mobilization and closure, but no leakage was seen after resection with primary anastomosis. Both mobilization of the bowel with resection of the affected part and anastomosis in granulation-free tissue appear to form the treatment of choice.

Angiotropin Treatment Prevents Flap Necrosis and Enhances Dermal Regeneration in Rabbits

Michael Höckel, MD, PhD, John F. Burke, MD

• Angiotropin is a potent angiogenesis factor isolated from the serum-free media of cultured, lectin-activated peripheral monocytes. In vitro, the purified substance stimulates migration, phenotypic differentiation, and tube formation, but not proliferation of capillary endothelial cells. When injected intradermally, angiotropin induces, in dose-dependent fashion, angiogenesis associated with skin hyperplasia. We have developed a flap model with insufficient blood supply and a model for contraction-free defect healing in rabbit skin. We show that (1) local pretreatment with angiotropin can prevent flap necrosis and (2) dermal regeneration after wounding can be augmented by angiotropin. From these results, we conclude that angiotropin might be of use as an adjuvant to healing in surgery.

(*Arch Surg* 1989;124:693-698)

Tissue ischemia due to impaired or reduced local blood flow is involved in the pathogenesis of a variety of diseases. It may also cause surgical complications, such as delayed wound healing, anastomotic insufficiency, or acute graft necrosis. Radiation-associated ulcer and fistula formation as well as major wound healing problems in burn patients are also consequences of insufficient microcirculation.

Since the discovery and isolation of biomolecules capable of inducing the neomorphogenesis of blood vessels ("angiogenesis factors"), a potential clinical use of these substances for the prevention or treatment of at least some of these pathological conditions has been suggested.[1] Moreover, biomolecules mediating angiogenesis and other cellular reactions involved in tissue regeneration and repair might also be applied to speed up normal wound healing processes.[2]

Angiotropin has recently been discovered as an angiogenesis factor acting on capillary endothelial cells in vitro by stimulating migration and differentiation into tube-forming cell phenotypes.[3] It has been isolated and highly purified from conditioned serum-free media of large-scale cultures of porcine peripheral monocytes activated with concanavalin A by Wissler et al.[4] Chemically, angiotropin was found to be a metallopolyribonucleopolypeptide complex consisting of one copper ion per 38 amino acids and 43 ribonucleotides as a least-common unit of all components. Selective enzymatic splitting indicated that the polypeptide as well as the polyribonucleotide portions are essential for the angiogenic activity.[4]

Intradermal injection of angiotropin into the skin of rabbit ear lobes in the concentration range of 1 to 20 ng/mL induces "controlled angiogenesis" in terms of defined time-dependent dynamics and dose-dependent vascular changes. These are characterized by an extension of the vascular bed and subsequent increase of blood perfusion, which is initially caused by dilation of the microvessels into large sinusoidal blood channels and later by local capillary growth.[5]

Angiotropin did not exhibit mitogenic activity on endothelial cells and fibroblasts in vitro when injected intradermally into rabbit skin.[3] Autoradiographic studies with tritiated thymidine demonstrated a strong increase of labeled endothelial cells, pericytes, and perivascular cells as well as stromal and epidermal cells. Within the site of angiotropin injection, resting hair follicles were activated to grow.[5,6]

The effects observed in the skin after intradermal injection of angiotropin prompted us to test the possibility that ischemic necrosis might be prevented and that the proliferative reaction in tissue regeneration/repair could be accelerated by use of angiotropin. We therefore studied the effects of angiotropin treatment in a miniflap model with inadequate vascular supply and in a model for contraction-free dermal regeneration.

MATERIALS AND METHODS

Animals

In our study we used adult long-eared New Zealand white rabbits of both sexes that weighed 2.5 to 3.5 kg and were kept in accordance with institutional guidelines. For the injections and operations, the animals were anesthetized by intramuscular application of 40 mg/kg of ketamine sodium (Ketanest, Parke Davies Co, Munich, West Germany) and 5 mg/kg of xylazine (Rompun, Bayer, Leverkusen, West Germany).

Intradermal Injections

After removing the hair with a depilatory (PILCA, Olivin Co, Hamburg, West Germany) and disinfection with povidone-iodine

Accepted for publication July 6, 1988.

Fig 1.—Design of flap model in ear lobe of rabbit. Racket-shaped whole-skin perichondrial tissue flap is raised from cartilage (A and B) and resutured in its former bed (C and D).

solution, intradermal injections were made in the skin of the dorsal aspect of the ear lobes. The injections were placed approximately at the junction of the middle and distal third of the ear and located to avoid visible blood vessels. The injections were done under direct vision.

A sterile 50-mL glass syringe (Hamilton, Bonaduz Co, Switzerland) was equipped with a 31-gauge needle. A shorter, 26-gauge needle was inserted into the epidermis at a low angle to serve as trocar, and the 31-gauge needle was directed through the trocar and pushed forward into the dermis for about 2 mm. The standard 50-mL aliquot injection produced a transient papule of about 1 cm in diameter.

Angiotropin

The preparation of angiotropin used in this study was shown to migrate as a single band in sodiumdodecyl sulfate polyacrylamide gel electrophoresis (SDS PAGE) gel[3] and to possess no endotoxin-like activity in the rabbit fever test. It was stored as frozen stock solution at a concentration of 50 ng/mL and dissolved in 1 mmol/L of L-cysteine and 3.65 mmol/L of pyrogen-free porcine serum albumin[8] as carrier protein. Thawed aliquots of stock solution were diluted with sterile pyrogen-free phosphate-buffered saline solution (GIBCO Inc, Grand Island, NY) prior to intradermal injections for the flap experiments. For the neodermis experiments, aliquots of the undiluted stock solution were used.

Flap Model

Dorsal aspects of both ear lobes were depilated and disinfected and racket-shaped full-thickness skin flaps, including the perichondrial tissue, were dissected from the cartilage (Fig 1, A and B). The diameter of the circular part of the flap was 10 mm; pedicle length, 2 mm; and pedicle width, 1.5 mm. Via a template flap, size and design were kept constant for all experiments. After hemostasis by gentle pressure with a gauze swab for three minutes, the flaps were reattached to their former beds with 6-0 monophilic single sutures (Fig 1, C and D). Wound dressings were not applied.

Inadequate perfusion of the transplants was achieved in the control experiments under the following conditions: The flaps were placed in the upper third of the dorsal aspect of the ear lobes of adult animals medially or laterally to the central ear artery. The skin at the transplantation site contained only hair follicles in the resting state. The location of the pedicle was chosen so that no macroscopically detectable vessel leading through it entered the circular part of the flap.

The rabbit ears were pretreated in the area of the future flap as follows: After the intended location of the transplant was drawn on the skin (Fig 2, D), two intradermal injections of 50 mL of phosphate-buffered saline solution containing 5 ng/mL of angiotropin and 25 mg/mL of porcine serum albumin were made in the prospective pedicle area and the center of the circular area. The angiotropin injections were repeated at the same sites 48 hours later. The flap experiments were performed 48 hours after the second injections of angiotropin. For the control experiments in the homologous sites of the contralateral ears, analogous injections were made with the carrier solution (phosphate-buffered saline and 25 mg/mL of porcine serum albumin) alone. All injected solutions were sterile and pyrogen free. The base of all flaps was placed at the distal margin of the ear.

Flaps were clinically judged each day for a ten-day period; the sutures and all necrotic tissue were then removed. Flap survival was judged by two investigators who did not know the mode of treatment.

Neodermis Model

In the depilated and disinfected dorsal skin of the rabbit ear lobe, an 8-mm circular defect was made that included the peri-

Fig 2.—Prevention of total flap necrosis by angiotropin in flap model. A, B, and C, Control ear. D, E, and F, Treated ear. See text for details.

chondrial tissue and denuded the cartilage (Fig 3, A and B). The defect was then covered by an equally sized graft of "artificial skin" fixed by 6-0 monophilic single sutures (Fig 3, C and D).

The operations were performed under strictly aseptic conditions on homologous sites of both ear lobes, each rabbit serving as its own control. One ear of each animal received an artificial skin graft that contained either 0.25 ng or 0.5 ng of angiotropin to test for a dose-related response. Only the carrier solution was added to the artificial skin graft of the control ear. No dressings were used to cover the artificial skin grafts.

On days 7 to 10, when loosening of the sutures was evident, the animals were killed for histologic examination by an overdose of pentobarbital sodium (Nembutal, Ceva Co, Paris). Fibrovascular ingrowth into the artificial skin matrix was determined morphometrically by measuring the area covered by "neodermal" tissue continuous to the primary wound margins with a computer-aided MOP videoplan (Kontron Co, Zurich). Morphometry was performed in Masson trichrome–stained paraffin sections of the whole ear, which were cut in the midline planes perpendicular to the long ear axis. The evaluation was done by two investigators who did not know the mode of treatment.

RESULTS

Flap Model

In all eight control experiments, no change of the vascular pattern could be observed preoperatively (Fig 2, A). Within 24 hours, all skin flaps became gangrenous (Fig 2, B), and after removing the sutures on the tenth postoperative day, the black and dry skin flaps stripped off, leaving a circular defect to the cartilage (Fig 2, C). The wound margins were covered by small rims of epithelialized granulation tissue. In only one case a narrow tongue of granulation tissue, extending from the edge, reached the center of the defect.

Corresponding flap experiments were performed at homologous sites of the contralateral ears. The sites, however, were pretreated with intradermal injections of a total of 1 ng of angiotropin, which resulted in marked engorgement of the microvascular bed within the skin sites where the flaps were raised (Fig 2, D).

After 24 hours, the flaps usually were somewhat edematous (Fig 2, E). Small focal demarcation areas were found in four treated transplants at that time. When the sutures were removed on the tenth postoperative day, four of eight skin flaps had healed completely, with intact epidermis and hair follicles (Fig 2, F). The remaining four flaps showed only epithelial defects of less than half of each transplant's area. However, the sites with impaired epidermis were covered by viable (bleeding) tissue. The tissue was continous to the wound edge corresponding to intact deeper layers of the dermis and/or granulation tissue. No overall skin defect denuding the cartilage was seen, as was the case in all untreated control flaps. The blindly evaluated results demonstrate a highly significant ($P = .0002$, Fisher's exact test) reduction of skin-flap necrosis following pretreatment with angiotropin.

Neodermis Model

Of the 14 experiments performed with this model, two cases had to be excluded because of local infection. A third case was also discarded because the animal damaged the artificial skin grafts by scraping. The results with the remaining 11 animals were evaluated in Masson trichrome–stained histological sections of the whole-ear specimens containing the artificial skin grafts in midplane transverse sections. The histological slides of a typical experiment are shown in Fig 4.

The fibrovascular tissue expanding into the artificial skin matrix (neodermis) could clearly be distinguished from the wound margins at the periphery and from the "empty" parts of the artificial skin matrix in the center (Fig 4, A and B). As a rule, the neodermis originated from the adjacent dermal and perichondrial wound margins. Occasionally, in the area of denuded cartilage, there was a small blood vessel perforating from the volar site of the ear through the cartilage. In a few cases, a small amount of fibrovascular tissue grew through these small holes in the cartilage, as seen in Fig 4, A (arrowhead). However, the

Fig 3.—Design of neodermis model in ear lobe of rabbit. Whole-skin perichondrial tissue defect denuding cartilage is made (A and B) and covered by equally sized artificial skin graft (C and D).

contribution of the tissue that grew through these small holes in the cartilage to the overall formation of the fibrous tissue ingrowth was not important.

In the majority of the control experiments, the wound margins were covered by a downward-growing, irregular epidermal layer that even reached the cartilage in some cases (Fig 4, A). Only small areas of the artificial skin matrix were filled with fibroblastic cells. Blood vessels were rarely found in the artificial skin grafts that contained only the carrier solution.

In the artificial skin grafts soaked with 0.5 ng of angiotropin, most of the matrix was filled by neodermal tissue (Fig 4, B). At the periphery, the original collagen fibers of the matrix were replaced by a loose network of newly synthesized fine collagen fibrils. Many fibroblasts and dilated neocapillaries were seen herein (Fig 4, C). Fibroblastic cells admixed with mononuclear cells filled the pores of the artificial skin matrix toward the center (Fig 4, D).

The fibrovascular ingrowth from the margins of the primary defects into the artificial skin matrix was determined morphometrically. The results obtained by two investigators who did not know the mode of treatment are shown in the Table. Neodermis formation was significantly ($P = .0039$, signed rank test) increased in the grafts containing angiotropin. The relative increase of the neodermis formation (mean ± SD) compared with the controls was 235% ± 39% when the artificial skin grafts were treated with 0.5 ng of angiotropin and 73% ± 37% when 0.25 ng of angiotropin was used, demonstrating the dose dependence of the angiotropin effects ($P = .047$, rank sum test).

COMMENT

Based on the in vivo actions of purified monocytic angiotropin—angiogenesis associated with tissue proliferation—we designed a pedicle flap and a skin graft model in rabbits with respect to a potential clinical relevance of this bioactive substance in surgery. With the flap model, we could demonstrate that ischemic necrosis due to the reduction of the microvasculature flow via surgical procedure was prevented by local pretreatment with angiotropin. In this model, the microvessels of both the graft and its bed were expanded by angiotropin treatment prior to the operation. The survival of the flaps pretreated with angiotropin compared with that of the controls might therefore be explained by (1) the enlarged vascular flow in the pedicle, providing increased perfusion of the flap with blood immediately after the operation, and (2) the presence of "activated" blood vessels or capillary sprouts at the time of surgery, leading to an earlier fusion of the blood vessels

of the flap with those of the surrounding wound margins.

The effects of angiotropin treatment in this model show remarkable morphological similarities with the "delay" phenomenon.[7,8] The mechanisms responsible for the improved survival of delayed whole-skin flaps are not fully understood at present. Although α-adrenergic vascular effects, as well as many others, are reported to be involved, a role for angiotropin or related substances in mediating the vascular effects of the delay phenomenon appears to be possible as well. Further studies must test this hypothesis.

This is, to the best of our knowledge, the first study that demonstrates the successful use of a purified angiogenesis factor to prevent tissue necrosis caused by insufficient microvascular supply. "Therapeutic" angiogenesis with physiological angiogenesis factors, such as pharmacological agents, appears to be a promising new approach as an adjuvant means in surgery.

The neodermis model was designed to demonstrate effects of angiotropin treatment on stromal tissue regeneration. It provided this information through quantitative determination of the ingrowing fibrovascular tissue by morphometry. Since the defects in the rabbit skin were extended below the perichondrium down to the cartilage, their geometry was anatomically defined in all planes. By use of the artificial skin matrix, wound contracture that otherwise might have interfered with the morphometrical evaluation could be avoided. In animal and human series, it was shown that artificial skin, a collagen chondroitin-6-sulfate matrix developed by other investigators,[9-13] leads to "regenerationlike" repair without skin contracture. Moreover, by soaking the artificial skin matrix with angiotropin solution, a homogeneous local application to the wound margins was achieved.

By use of the model, we found that angiotropin stimulates the growth of connective tissue into the artificial skin, resembling dermis, in dose-dependent fashion. These results also show that the tissue defect is not the maximal stimulus for regeneration or repair and that wound healing can be accelerated by chemical mediators used as local pharmacological agents. Considering the cellular effects of angiotropin in vitro[3] and in vivo,[5] we suggest that the stimulation of fibrovascular ingrowth into the artificial skin matrix is due to the increased activation of endothelial cells of capillaries in the undamaged wound margins. Angiotropin-activated microvascular endothelial cells can be hypothesized to provide cellular signals for tissue proliferation via several proposed mechanisms.[5] This point remains to be tested.

The successful use of (angiogenic) growth factors to accelerate dermal and epidermal wound healing has been reported recently.[14-22] However, these growth factors had to be applied in greater than 1000-fold–higher doses to produce a stimulation of wound healing comparable with that of angiotropin treatment. Angiotropin is therefore regarded as a very potent accelerator of dermal wound healing and should be tested in further studies with respect to its use for clinical situations where wound healing is a major problem.

Angiotropin and artificial skin were provided by J. J. Wissler, Bochum, West Germany, and Marion Laboratories, Kansas City, Mo, respectively.

Dr Höckel thanks V. Friedberg, MD, Mainz, West Germany, for generous support of this work.

The authors thank D. Costa and G. Kind for excellent technical assistance and R. Lippold, Institut für Statistik und Medizinische Dokumentation, Mainz, for his help with the statistical evaluation of the data.

We acknowledge the critical reading of the manuscript by P. Vaupel, PhD, Harvard Medical School, Boston.

Simple Intestinal Obstruction Causes Bacterial Translocation in Man

Edwin A. Deitch, MD

• **Indirect clinical evidence has accumulated indicating that the gut may be a reservoir for microorganisms causing systemic infection in man. Our experimental results, in a variety of animal models, demonstrate that bacteria can translocate across the mucosal barrier and cause systemic infections. To determine directly whether bacterial translocation occurs in man, we cultured mesenteric lymph nodes (MLNs) obtained at laparotomy from 42 patients, none of whom were clinically infected. Ten (59%) of 17 patients with intestinal obstruction (none of whom had necrotic bowel) had bacteria in their MLNs, in contrast to one (4%) of 25 patients operated on for other reasons. The most common bacteria cultured from the MLNs was *Escherichia coli*. Thus, it appeared that simple intestinal obstruction of the colon or small bowel in the absence of necrotic bowel was associated with bacterial translocation.**

(*Arch Surg* 1989;124:699-701)

Under normal circumstances, the gut performs many functions, including the complex processes of digestion, selective absorption, and secretion. However, the gut contains bacteria and bacterial products that must be excluded as well as nutrients that must be absorbed. Therefore, the gut has developed a complex immune system that works in synchrony with local antibacterial barrier systems to prevent the escape of luminal contents. Although it is well recognized that intestinal motility, absorption, and secretion may be altered, it has only recently been recognized that the gut's immunologic and barrier functions may also fail.[1,2]

We have demonstrated experimentally that indigenous bacteria colonizing the gastrointestinal tract can cross the epithelial mucosa to infect the mesenteric lymph nodes (MLNs) and systemic organs, a process termed *bacterial translocation*.[3,4] Factors that promote the translocation of bacteria from the gastrointestinal tract in animal models include disruption of the ecologic balance of the normal indigenous microflora, resulting in bacterial overgrowth,[4,5] impaired host immune defenses,[6] physical disruption of the gut mucosal barrier,[7] trauma,[8] endotoxemia,[9] intra-abdominal abscesses,[10] and hemorrhagic shock.[11,12] Furthermore, systemic sepsis occurred in endotoxin-challenged, protein-malnourished, or immunocompromised mice, since the spread of bacteria from the gut could not be controlled and the translocating bacteria could not be cleared.[1,2] Thus, in some experimental circumstances, bacteria translocating from the gut caused septicemia and death. In addition, indirect clinical evidence has accumulated indicating that the gut may be a reservoir for microorganisms causing systemic infections in man.[2,13,14] To determine whether bacterial translocation occurs in man, we quantitatively cultured MLNs from 42 noninfected patients undergoing laparotomy. The results of this study indicate that intestinal obstruction is associated with bacterial translocation to the MLN in the absence of intra-abdominal infection.

PATIENTS AND METHODS

At laparotomy, the MLNs of 42 patients operated on between April and November 1987 for a variety of conditions underwent biopsy. Patients with an intra-abdominal infection, necrotic bowel, or a perforated viscus were excluded from study. All patients received perioperative antibiotics. At the time of laparotomy, prior to performance of any further operative manipulations, a lymph node from the mesentery of the small or large intestine was excised and sent for culture. Cultures of peritoneal fluid when present were obtained in patients operated on for intestinal obstruction.

The excised lymph node was immediately taken to the laboratory, where it was weighed and then placed into grinding tubes containing sterile tryptic soy broth and processed as previously described.[3,4] Briefly, the MLN was homogenized with glass-reinforced Teflon grinders, and aliquots (0.3 mL) of the MLN homogenate were plated on selective MacConkey agar to culture gram-negative, enteric bacilli, on blood agar to culture gram-positive cocci, and on selective agar to culture lactobacilli. The plates were incubated at 37°C for 24 hours. Three milliliters of tryptic soy broth was added to the remaining 0.1 mL of MLN homogenate and incubated overnight at 37°C. Any growth was gram-stained and subcultured on MacConkey agar. The gram-negative, enteric bacteria were identified with an enteric (API 20E) identification system and gram-positive cocci and lactobacilli were identified by standard procedures. Strict anaerobic bacteria were not measured, since obligate anaerobic bacteria rarely translocate from the gut.[15] The translocation levels of the

various bacteria were calculated per gram of MLN. Comparisons between groups were performed by χ^2 analysis.

RESULTS

The 42 patients were divided into two groups according to whether or not intestinal obstruction was present. Only one of the 25 patients, who did not have intestinal obstruction, had viable bacteria in her MLN (Table 1). This patient had previously received radiation therapy and chemotherapy for an ovarian carcinoma and the current procedure was an elective cholecystectomy for symptomatic cholelithiasis. Thus, with the exception of the patient who had received intestinal radiation therapy, the MLNs of patients without intestinal obstruction were sterile.

Of the 17 patients operated on for intestinal obstruction, the small bowel was the most common site of obstruction (71%) (Table 2). None of the patients with small-bowel obstructions had necrotic bowel or required intestinal resections. The incidence of bacterial translocation to the MLNs of the patients with intestinal obstruction (59%) was significantly higher than in the patients without intestinal obstruction (4%) ($P<.001$). The presence of bacteria in the MLN was not due to surface contamination with intraperitoneal bacteria, since peritoneal fluid cultures were sterile in nine of the ten patients with small-bowel obstruction who had peritoneal fluid cultures performed. The MLN was sterile in the patient who had a positive peritoneal fluid culture. In fact, this peritoneal fluid specimen contained *Staphylococcus aureus*, an organism that was not cultured from any of the MLNs. The most common bacterium cultured from the MLNs of these patients was *Escherichia coli*, which was present in eight of the MLNs (72%) containing viable bacteria (Table 3).

There was no apparent clinical difference between the six patients with small-bowel obstructions who had sterile MLNs and the six patients whose MLNs contained bacteria. The mean (±SD) age of the patients with sterile MLNs was similar (59±15 years) to that of the patients (55±21 years) with bacteriologically positive MLNs, as were their clinical histories and preoperative findings. None of the patients from either group developed postoperative intra-abdominal infections.

Table 1.—Incidence of Bacterial Translocation ot MLNs* in 25 Patients Undergoing Elective Surgery

Organ System	n	Incidence of Translocation
Biliary tract	10	1
Pancreas†	6	0
Stomach	3	0
Colon	3	0
Aorto-iliac	3	0

*MLNs indicate mesenteric lymph nodes.
†Three patients had cancer and obstructive jaundice; two patients had pancreatic pseudocysts; and one patient had pancreatitis.

Table 2.—Incidence and Magnitude of Bacterial Translocation to MLNs* in 17 Patients Operated on for Intestinal Obstruction

Intestinal Segment	n	Incidence of Translocation	CFUs per Gram of MLN†

Enterobacter aerogenes and *Citrobacter freundii*	1	SBO

*MLNs indicate mesenteric lymph nodes.
†One patient had gastric outlet obstruction; two patients had obstructing colon cancers; and one patient had small-bowel obstruction (SBO).

COMMENT

The results of this study indicate that the MLNs draining the small and large intestine generally do not contain viable bacteria. However, intestinal obstruction will promote the translocation of bacteria from the intestine to the MLNs, since 59% of the patients with simple intestinal obstruction had viable bacteria cultured from their lymph nodes. The presence of bacteria within the lymph nodes was not due to contamination by intraperitoneal bacteria, since the peritoneal cavities of all but one of these patients were sterile. In fact, the incidence of bacteria translocation may have been underestimated for two reasons. First, all of these patients received perioperative antibiotics and second, only one lymph node was cultured per patient. Thus, if antibiotics were not used and/or more lymph nodes had had biopsy specimens taken from them, the incidence of bacterial translocation may have been higher.

The results of the present study are similar to those reported by Ambrose et al,[16] who sampled ileal serosa and MLNs from patients with or without Crohn's disease. They found that only 5% of the patients without Crohn's disease had viable bacteria in their MLNs, in contrast to the patients with Crohn's disease, in whom 33% of the MLNs contained bacteria. These authors concluded that leakage of bacteria from the gut lumen may be responsible for the high incidence of intra-abdominal infections in this group of patients. Unfortunately, information is not available on the indications for surgery in those patients with Crohn's disease. Therefore, the possible role of intestinal obstruction in the escape of bacteria from the gut in these patients cannot be determined. Nevertheless, there is no evidence from two studies indicating that, under certain circumstances, bacteria can translocate from the gut to the MLN in man.

To our knowledge, the mechanism(s) responsible for the translocation of bacteria from the gut to the MLN in patients with intestinal obstruction is not known. Based on our previous animal studies,[2,4,7,9,11] however, it is likely that intestinal obstruction induces bacterial translocation by promoting bacterial overgrowth, increasing intestinal permeability, or physically disrupting the mucosal barrier. Which of these mechanisms are operative will require further study both in animals and in man.

In the 1960s Caridis et al[17] and Woodruff et al[18] proposed that bacteria and endotoxin could leak from the intestines into the systemic circulation in certain disease states. Since the early anecdotal studies of these authors, several epidemiologic studies have been reported documenting that bacteria colonizing the gut can cause systemic infections in bone marrow recipients and in patients with cancer.[13,14] Life-threatening infections with gut-associated bacteria are not limited to bone marrow recipients and patients with cancer. Patients who have undergone surgery also frequently develop bacteremias for which a source of infection is never found even at autopsy. These high-risk patients include patients who have sustained burns,[19,20] victims of trauma,[21] and patients developing multiple organ failure.[22,23] The patient populations at increased risk of developing bacteremias from clinically occult foci tend to share certain common predisposing factors, including an immunocompromised state, altered intestinal function, and previous exposure to therapeutic regimens that may have altered the ecology of the indigenous gut flora. Thus, indirect clinical evidence has accumulated indicating that the gut may be a reservoir for microorganisms causing systemic infections in man.

The current study presents direct evidence that bacteria can translocate across the intestinal barrier and spread to the MLNs in patients with simple intestinal obstruction in the absence of necrotic bowel or bacteriologically positive peritoneal cultures. These findings add further support to the hypothesis that systemic infections may be caused by microorganisms translocating across the intact gut.

This investigation was supported by grant GM36376 from the National Institutes of Health, Bethesda, Md.

Cancer of the Nongastric Hollow Organs of the Gastrointestinal Tract After Gastric Surgery

Ravi Thiruvengadam, MD; Victoria Hench, MS; L. Joseph Melton III, MD; Eugene P. DiMagno, MD

To estimate the risk of esophageal, gallbladder, small-bowel, and colon cancers after gastric surgery for benign disease, all 337 residents of Olmsted County, Minnesota, who had surgical treatment of benign peptic ulcer disease during the years 1935 through 1959, were followed up. Patients were followed up for 6552 person-years of observation. No esophageal cancers developed (0.8 were expected). Members of the cohort developed one small-bowel malignant neoplasm (0.2 were expected), two gallbladder cancers (1.1 was expected), and four colon cancers (11.2 were expected), but these figures do not reflect a significant increase in the risk of these malignant neoplasms. In particular, the relative risk of developing colon cancer was only 0.4 when this analysis had 88% power to detect a relative risk of two or more. When the present investigation and two previous studies of this cohort were taken together, there was no strong evidence for an increased risk of any gastrointestinal cancer following gastric surgery (*Arch Intern Med* 1988;148:405-407).

Management of Severe Incisional Abscesses Following Laparotomy

Early Reclosure Under Cover of Metronidazole and Ampicillin

Finn Gottrup, MD, PhD; P. Gjøde, MD; F. Lundhus, MD; H. Andrup, MD; C. N. Holm, MD; S. Terpling, MD

• Patients developing severe incisional abscesses following laparotomy were treated with incision and drainage followed by early reclosure under antibiotic cover with metronidazole and ampicillin anhydricum. Patients with subcutaneous abscesses were randomized into two groups that were treated with antibiotics for one day (n = 23) or four days (n = 27). These patients all underwent reclosure four days later. In a third group of patients (n = 14) abscesses had developed down to, but not through, the peritoneum. These patients received antibiotic treatment for four days and underwent reclosure a mean of 5½ days later (range, four to eight days). No abscesses reappeared in any group and all wounds healed by first intention. Five patients healed totally, with minor defects, but there was no need for surgical intervention. We conclude that the early reclosure technique is a safe procedure under antibiotic cover with metronidazole and ampicillin. One day and four days of antibiotic treatment are equally safe in patients with subcutaneous abscesses.

(*Arch Surg* 1989;124:702-704)

Early reclosure of incisional abscesses, before granulation tissues become visible, is biologically comparable to delayed primary closure of wounds. This surgical procedure increases the resistance of the wound against infection and improves healing of the wound. The resulting appearance of the wound is comparable to that of an uncomplicated, primarily healed wound.[1] Early reclosure of contaminated wounds four days after drainage of severe incisional abscesses down to the fascia following laparotomy has recently been described in retrospective studies.[2,3] In those studies, clindamycin phosphate was administered for four days. However, this drug is bacteriostatic, and severe side effects have been described.[4] To our knowledge, no prospective studies on early reclosure of subcutaneous abscesses breaking through the fascia have been published.

In this randomized, prospective, double-blind study, early reclosure under antibiotic cover with metronidazole and ampicillin anhydricum for one or four days was performed on incisional wounds extending to the fascia. In all cases where the abscess broke through the fascia, but the peritoneum was intact, the antibiotic was administered for four days.

PATIENTS AND METHODS

This study was carried out over a period of 20 months from 1985 to 1987. Seventy-three consecutive patients with severe incisional abscesses following laparotomy were randomized into groups 1 and 2, with abscesses to the fascia, and group 3, where the abscess went through the fascia but the peritoneum remained intact. Severe incisional abscess was defined as an accumulation of pus necessitating surgical opening of the wound. All wounds were drained of pus and cleaned daily. After four days in groups 1 and 2 and four to eight days in group 3, patients underwent the excision of necrotic tissue. The wounds were closed using interrupted polypropylene (Prolene) sutures. In groups 1 and 2 a large needle was passed through the skin and subcutaneous layer at a distance of 2.5 cm to 3 cm from the wound margins and underneath the fascia (Figure). In cases where the fascia was broken (group 3), it was reclosed by interrupted polyglycolic (O-Dexon) sutures. These surgical procedures allowed complete occlusion of the wound cavity with few or no sutures in the cavity itself.

The antibiotic cover consisted of 500 mg of metronidazole and 1 g of ampicillin anhydricum, both administered three times daily. Five hundred milligrams of metronidazole and 1 g of ampicillin were administered half an hour preoperatively and every eight hours thereafter. The antimicrobial agents were administered intravenously on the day of resuturing. On postoperative days 1, 2, and 3, metronidazole and ampicillin were administered as suppositories and capsules in group 2, while in group 1, placebo suppositories and capsules were administered. In group 3, all patients were treated with antibiotics for four days.

While the patients were hospitalized, daily postoperative observations of the wounds were performed. Sutures were removed on the tenth day and the patients were seen in the hospital eight weeks after reclosure to discover any delayed septic complications. During each observation, the wounds were observed for tissue reaction (swelling, erythema, or tenderness), pus accumulation, and defects of the incision line.

The investigation was conducted according to the Declaration of Helsinki II. The protocols and methods were accepted by the Danish National Health Service and the local committee concerning ethics in science.

The statistical evaluation included the χ^2 test applied with Yates' correction.

RESULTS

Of 71 patients meeting the criteria, four were excluded due to error of the surgical procedure and three were excluded due to error of the medical procedure, leaving 64 patients for study.

The groups were well matched in regard to age, sex, and primary operations (Table 1). Group 1 had a relatively higher percentage of women than groups 2 and 3. The results of the study are shown in Table 2. Forty-four patients (69%) had no tissue reaction, such as swelling, erythema, or tenderness, after ten days of healing, when the sutures were removed. No abscesses reappeared within 60 days, but five patients healed with minor defects, which were defined as defects less than one third the total wound length. Minor defects were found in three patients (21%) in group 3 and one each (4%) in groups 1 and 2. In no

Healed by first intention	23	27	14
Healed with minor defects (<⅓ length of incision)	1	1	3
Wound sepsis within 60 d	0	0	0

patients with minor defects of the healing wound was further surgical intervention needed. No fistula formation or other surgical complications were encountered during the observation period. Bacteriological findings of the primary infected wounds were similar to earlier reported bacteriological findings from our hospital departments.[4,5]

No significant differences were found between the three groups in regard to primary healing, recurring abscesses, or healing with minor defects.

COMMENT

In this study, early reclosure of incisional wounds down to and through the fascia has been shown to be a safe procedure under antibiotic cover with metronidazole and ampicillin. The results are similar to those of an earlier retrospective study using clindamycin as an antibiotic cover.[3] Compared with clindamycin, the metronidazole/ampicillin regimen is bactericidal, has few side effects, has a broad antibacterial spectrum covering almost all bacterias involved, and is inexpensive. Clindamycin is a bacteriostatic drug with a spectrum that includes anaerobic organisms and *Staphylococcus aureus*.[6] Our employment of ampicillin was based on our knowledge of the sensitivity of the predominant organisms isolated after colorectal surgery in our hospitals. *Escherichia coli* was isolated from most postoperative wound infections and the incidence of ampicillin resistance was about 15% for several years. This sensitivity of *E coli* to ampicillin is higher than that reported in England and the United States.[6,7] For this reason, selection of antibiotics always has to be based on the present sensitivity of the dominant organisms isolated from infections. Ampicillin has been shown to be effective against enterococci, but some strains of *S aureus* were resistant.[4]

The decision to close a contaminated wound is based on a few important factors: timing, technique of wound closure, and antibiotics.[1] The use of specific antibiotics is probably of minor importance compared with timing and closure technique. The wounds were resutured on the fourth day after they were opened and drained. This is in accordance with the principle of delayed primary closure, which is defined as closure that is delayed a few days but accomplished before granulation tissue becomes visible, usually eight to ten days after wounding.[1] Secondary closure refers to either spontaneous closure or closure by operation after granulation tissue has developed and the wound macroscopically looks "clean." This has been found 12 days after drainage of the wound abscesses.[3]

The ideal time for closure of contaminated wounds has experimentally,[8] as well as clinically,[9,10] been found to be on or shortly after the third or fourth day. Earlier closure will not allow the wound to be prepared for enhanced healing or resistance to infection.[11] In later closures (secondary closure), the wound edges will become increasingly difficult to approximate because the granulation tissue induces an increasing collagen content in the wound.

The closure technique used in this study is based on known surgical principles, such as débridement with removal of foreign bodies and devitalized tissue. Furthermore, the suture technique, without sutures in the wound itself, results in a complete occlusion of the wound cavity, thus inhibiting formation of hemorrhage or fluid collection. This has been shown to decrease the risk of infection in contaminated wounds.[12,13]

Future investigation will show whether a shorter dura-

tion of antibiotic administration is possible and whether the decrease in anaerobic infections allows us to use antibiotics not specificly directed against anaerobic organisms.

CONCLUSIONS

From this prospective study, we conclude that early reclosure after drainage of severe incisional abscesses of the subcutaneous space or through the fascia following laparotomy is a safe procedure under antibiotic cover. Early reclosure implies an improved cosmetic result as well as a reduction in hospitalization and convalescence.

We thank A/s Rhonê-Poulenc for supplying metronidazole (Flagyl) and A/s Gist-Brocades for supplying ampicillin (Anhypen).

Is Mammography Painful? A Multicenter Patient Survey

Paul C. Stomper, MD; Daniel B. Kopans, MD; Norman L. Sadowsky, MD; Marian R. Sonnenfeld, MD; Cynthia A. Swann, MD; Rebecca S. Gelman, PhD; Jack E. Meyer, MD; Maxine S. Jochelson, MD; Myla S. Hunt, MA; Paul D. Allen, MD, PhD

Anecdotal reports of pain experienced during mammography have been a source of anxiety and concern for some women considering screening. To determine what asymptomatic women actually experience during mammography, a survey of 1847 women was performed at seven breast-imaging centers. Women recorded their experience on a six-point scale ranging from no discomfort to severe pain. Eighty-eight percent of the women experienced no discomfort (49%) or mild discomfort (39%). Only 9% experienced moderate discomfort; 1%, severe discomfort; and 1%, moderate pain. No woman had pain so severe that it would make her reconsider having a mammogram again. The degree of discomfort was slightly greater in women who complained of breast tenderness within three days prior to the mammogram but was not strongly related to age, menstrual status, or week of the menstrual cycle. We conclude that in a vast majority of women mammography causes no or mild physical discomfort and that actual pain is an uncommon occurrence (*Arch Intern Med* 1988;148:521-524).

Oral Prophylaxis With Neomycin and Erythromycin in Colorectal Surgery

More Proof for Efficacy Than Failure

Per-Arne Kling, MD, Sven Dahlgren, MD

• In an open, prospective, and randomized investigation on the prophylactic efficacy of peroral neomycin sulfate–erythromycin base vs intravenous ceftriaxone-metronidazole preparation in colorectal surgery, no significantly diverging results between regimens were recorded (1/27 [3.7%] and 2/27 [7.4%] wound infections, respectively). Commentary is made about the diverging results from earlier studies on antimicrobial prophylaxis and on the multifactorial causality of surgical infection. We believe that variables such as physical condition of the patients, virulence and local resistance patterns of bacteria, and technical skill of the surgeons are far more important in regard to the postoperative outcome concerning septic complications than is the choice of proper antibiotics. Thus, to determine the efficacy of antimicrobial prophylaxis, we call for larger investigations in the future, preferably double-blind, where it is possible to better control and diminish the influence of determinants other than the antibiotics being compared.

(*Arch Surg* 1989;124:705-707)

Throughout the last 15 years, innumerable studies have been carried out to estimate the efficacy of different enteral and/or systemic antibiotic regimens for prophylaxis of infection in colorectal surgery. By tradition, enteral/peroral (PO) antimicrobial regimens have been, and probably still are, favored by many American surgeons, whereas systemic/intravenous (IV) prophylaxis has become more and more common in western Europe. Oral prophylaxis, which by tradition is paralleled by a thorough mechanical bowel-cleansing procedure, is theoretically aimed at lowering the bacterial counts in the colon lumen, thereby diminishing the bacterial inoculum in case of intraoperative spillage.[1] Intravenous preparation, on the other hand, does not necessarily include the same meticulous bowel-cleansing procedure, and the antimicrobial effect on the colonic bacterial flora is probably negligible, the aim instead being to achieve antibiotic concentrations in blood and tissues high enough to deal with the fecal spillage that might occur intraoperatively.

To compare the efficacy of these two main prophylactic regimens, a two-center trial was conducted in Birmingham (United Kingdom) and Umeå (Sweden) in 1985 to 1986. After identical mechanical bowel-cleansing procedures, one study group was orally prepared with three standard loading doses of erythromycin base and neomycin sulfate[2] (PO group), whereas the other group of patients was subjected to a single IV administration of metronidazole (Elyzol) and ceftriaxone (Rocephin, a rather new long-acting cephalosporin[3]; IV group). The original intention of the two-center investigation was to present a mutual study report after the entrance of about 100 patients in each group, with the reservation that for "safety reasons" a sequential analysis would be carried out and the study discontinued in case of "very high sepsis rates" in either prophylactic regimen.

As infection rates for the Birmingham PO group turned out to be unacceptably high, the study was concluded at the English center after the entrance of only 60 patients. At that time the preliminary Swedish figures were in no way alarming, and it was decided that our part of the investigation should not be discontinued until a comparable number of patients had been entered into the study. Results from the English center (41% wound infections in the PO group vs 9.6% in the IV group) were presented in 1986.[4] Since results from the Swedish study differ greatly from those obtained at the English center, we believe it is important that they be reported.

PATIENTS AND METHODS

This open, randomized study was undertaken at the Department of Surgery of Umeå University Hospital between May 1985 and December 1986. Only patients admitted for elective surgery for either colonic or rectal carcinomas were included in the study. A total of 63 patients were randomized. Nine of these patients were excluded from the final evaluation: six of them, three in each group, because their bowels were never opened at operation (exploratory laparotomy alone) and three patients, two from the PO and one from the IV group, because additional antibiotics were given within 48 hours after operation. In spite of minute inquiry, no obvious reasons for any of these additional antibiotic treatments were found. After these exclusions, the study comprised 54 evaluable patients, 27 in each group. The localization of carcinomas is given below:

	PO	IV
Cecum	4	4
Ascending colon	2	6
Transverse colon	3	0
Descending colon	2	1
Sigmoid	9	9
Rectum	7	7

Accepted for publication Oct 28, 1988.

From the Department of Surgery, Umeå University Hospital, Umeå, Sweden.

Reprint requests to Department of Surgery, University Hospital, S-901 85 Umeå, Sweden (Dr Kling).

The operative procedures performed were as follows:

	PO	IV
Right hemicolectomy	4	9
Ileotransversostomy	2	1
Transverse resection	2	0
Left hemicolectomy	3	1
Sigmoid resection	6	8
High anterior resection	3	1
Low anterior resection	3	2
Rectal amputation	3	5
Colostomy alone	1	0

The mean age for patients in the PO group was 70 years (range, 53 to 81 years) and for the IV group, 64 years (range, 44 to 81 years). The female-male ratio was 14:13 in the IV and 11:16 in the PO group. Diabetes mellitus was the only complicating disease found among the patients: four in the IV and five in the PO group.

Before surgery all patients were subjected to mechanical bowel preparation slightly modified from that described by Nichols et al[1] in 1972 (Table). Patient discomfort, if any, as well as bowel-cleansing efficacy, was followed up throughout the entire investigation.

Patients in the PO group were given 1 g of neomycin sulfate and 1 g of erythromycin base at 1, 2, and 11 PM on the day before operation. In the IV group, single doses of metronidazole (1.5 g) and ceftriaxone (2.0 g) were administered at the induction of anesthesia.

Immediately after surgery, all surgeons were questioned about the occurrence and quantity of fecal spillage during the operation. They were also asked about other possible surgical complications such as bleeding, unintentional damage to other structures, and other technical problems. All patients who entered the investigation were meticulously followed up for any signs of postoperative infection until at least six weeks after the operation.

Postoperative infection was monitored by a specially trained and experienced nurse-epidemiologist. Wound infection was defined as the discharge of pus, either spontaneously or by débridement. It was planned that intra-abdominal abscess formation, if any, would be monitored by ultrasonographic or computer tomographic examinations and ultimately diagnosed by relaparotomy. All infections directly related to the operative field are referred to herein as surgical infections. Material from infected sites was quickly taken to the bacteriological laboratory for routine aerobic and anaerobic cultivation. The occurrence of urinary (UTI) and respiratory (RTI) tract infections, designated herein as nonsurgical infections, was also monitored. Furthermore, fecal material randomly collected from 12 of the patients who received PO prophylaxis was specially examined during the postoperative course for the possible appearance of *Clostridium difficile* enterotoxin. The 54 evaluable patients were operated on by 22 surgeons, none with less than five years of surgical experience. Only one of the surgeons operated on more than ten patients in this investigation.

RESULTS

None of the six patients, three in the PO and three in the IV group, who were excluded because their bowels were not opened at operation experienced any postoperative septic complications. Among the three patients excluded as a consequence of early postoperative administration of antibiotics, only one, randomized to the PO group, had a nonsurgical infection (RTI) during the postoperative course.

Only three surgical infections occurred among evaluable patients (3/54, 5.6%): one perineal wound infection after rectal amputation in the PO group (1/27, 3.7%) and two perineal wound infections, one of them with extension also to the abdominal wound, in the IV group (2/27, 7.4%). No cases of septicemia were documented during the course of this investigation. In the PO group, the infecting organism was *Staphylococcus aureus*, whereas the two IV group infections were caused by *Escherichia coli* plus *Klebsiella aerogenes* and *Pseudomonas aeruginosa* plus *S aureus*, respectively. Anaerobic pathogens were not obtained from any of the surgical infection sites. In the IV group, one patient was operated on for ileus 20 days after the primary operation. Although there were no signs of intra-abdominal infection at the time of this relaparotomy, for unknown reasons imipenem was instituted in the postoperative course.

In the PO group, five patients developed UTI. Three of them were given antibiotic treatment with trimethoprim-sulfamethoxazole and one received amdinocillin pivoxil. One patient with UTI recovered without antimicrobial treatment. In none of the UTI cases were antibiotics instituted before the tenth postoperative day, and none of the nonsurgical infections gave rise to any septic complications.

Clostridium difficile enterotoxin was not isolated from any of the fecal samples randomly obtained from patients in the PO group, and no patients suffered from postoperative diarrhea. On the other hand, 11 patients (11/54, 20%) experienced discomforting diarrhea from the preoperative bowel-cleansing procedure. In both the PO and the IV groups, the cleanness of the bowel was considered very good in 22 patients (44/54, 81.5%) and poor or bad in five patients from each group; all the latter had stricturating carcinomas in the rectosigmoid colon. Fecal spillage was considered insignificant in 20 patients in the IV group and 22 in the PO group. A fairly large spillage was registered in five patients in the IV group and five in the PO group, whereas in two in the IV group the spillage was considered to be massive. The latter two patients—both with rectal amputations, one of them suffering from diabetes mellitus—constituted the infected cases in the IV group. For the only surgical infection occurring in the PO group, also a rectal amputation, the intraoperative spillage was reported as insignificant.

Mechanical Bowel Preparation

Day	Regimen
1	Low-residue diet; bisacodyl, 5 mg orally at 6 PM
2	Continue low-residue diet; magnesium sulfate, 7 g orally at 10 AM, 2 and 6 PM; water enema in evening
3	Clear liquid diet; magnesium sulfate, in above dose, at 10 AM and 2 PM; no enemas
4	Rectal washout at 6 AM; operation

COMMENT

Following the first presentation by Nichols et al[1] in 1972 on the subject of neomycin-erythromycin bowel preparation in colorectal surgery, the beneficial effects of this regimen on the postoperative infection rate have been confirmed by several investigators. By far the largest and most impressive tribute to the idea of "gut sterilization" was given by Condon et al,[5] who in 1983 presented results from a multicenter study comparing the efficacy of oral neomycin-erythromycin with and without the addition of IV cephalothin (5.7% and 7.8% infectious complications, respectively). The significance of these results is underlined by the fact that each study group contained more than 540 patients, an unusually large number for this kind of investigation. In a recent European investigation on the same topic, Figueras-Felip et al[6] presented results from a study with one tenth the number of patients comparing

the standard neomycin-erythromycin PO preparation with IV gentamicin-metronidazole prophylaxis. They found significantly fewer wound infections in the PO than in the IV group (5% and 21%, respectively; $P<.05$).

In regard to systemic prophylaxis, the number of antibiotic combinations, investigators, and study designs has been considerable during the last ten years. It is not so far-fetched to assume that the large number of investigations containing few patients is simply a reflection of the ceaseless flow of new and potent antibiotics from manufacturers, and an eagerness to achieve rapid results to get the antibiotics registered also for prophylaxis of infection within the broad field of gastrointestinal surgery. These factors are open for discussion, since development of postoperative infection after contaminated surgery is most certainly a question of multifactorial causes, and the choice of proper antibiotics constitutes only one of these. Variables difficult to standardize, such as the physical condition of the patients, disease state, virulence and resistance patterns among fecal pathogens, and differences both in surgical conditions and in technical qualifications of the surgeons, are probably far more decisive in regard to postoperative outcome than is the choice of proper prophylactic antibiotics. This constitutes neither a lack of approval for antibiotics in contaminated surgery nor a denial of the fact that different antibiotics may be more or less effective against fecal pathogens, but merely a claim for larger studies (multicenter, double-blind studies involving centers with genuine interest in these problems) to determine the significance of the above-mentioned uncontrollable variables. In our rather small study on the efficacy of PO and IV antimicrobial prophylaxis, we were unable to detect any difference between the regimens. Our results for the PO group are in sharp contrast to those obtained by our Birmingham colleagues (one of 27 infected PO cases in Umeå vs 14 of 29 in Birmingham; $P<.001$). We have not been able to discover any plausible explanation here at the Swedish center for this large difference in results between two identical studies based on a common study protocol.

One gets the impression from many investigations that traditional PO prophylaxis is effective in significantly lowering postoperative morbidity from infectious complications in elective colorectal surgery. We also know from several studies that both single and multiple doses of IV antibiotics (such as metronidazole for anaerobes and third-generation cephalosporins for aerobes) have likewise proved effective in lowering infection rates after contaminated surgery. Furthermore, neither the PO nor the IV regimen has proved harmful to the patients or to the ecology of the fecal flora of the patients. Thus, it is somewhat surprising that the emergence of resistance to neomycin and erythromycin, which was observed and made responsible in part for the discouraging Birmingham PO figures, did not give rise to related problems in the multicenter trial performed by Condon et al.[5]

Perhaps the correct answer to the question as to whether to use the American (PO) or the European (IV) model for antibiotic prophylaxis should be to use both, ie, a thorough mechanical bowel-cleansing procedure, PO neomycin-erythromycin on the day before operation to reduce colonic bacterial counts, and single-dose systemic antibiotics administered preoperatively to achieve high enough antibiotic concentrations in blood and tissue to deal with the spillage that sometimes is difficult to avoid in a potentially contaminated operative field.

Editorial Comment

This is a report of a study of 54 patients in a randomized clinical trial comparing PO neomycin-erythromycin with IV ceftriaxone-metronidazole for antibiotic bowel preparation in patients undergoing elective resections for cancer. The study showed no significant difference in postoperative infectious complications between the two study groups. Under usual circumstances, this report would not be of great interest, primarily because of the small numbers of patients involved. However, there are special circumstances surrounding this report.

This report from Sweden gives the results from a part of a multi-institutional trial, the other part of which has previously been reported from Birmingham.[1] What makes the present article interesting, and justifies its publication, is the disparity in results between Umeå and Birmingham. The Birmingham part of the study, which was published without referring to the fact that another institution was also participating in the trial, showed an unexpectedly high postoperative infection rate following PO bowel preparation.[2] The reason for this result, which is clearly different from the experience with PO antibiotics in many other institutions around the world, was never satisfactorily explained by the Birmingham authors.[3] The explanation still remains obscure.

This report from Umeå documents a second instance in which the Birmingham group has participated in a multi-institutional trial, and reported their results unilaterally, with a disparate experience as compared with the other institution. The previous example was a report comparing IV vs PO regimens of kanamycin-metronidazole. Very different results were obtained between Birmingham[4] and Switzerland.[5]

It is important for surgeons to realize that the results from studies of infections following surgical procedures, as reported from some institutions in Britain today, are unique. The reasons for this phenomenon are not immediately apparent. Indeed, one can only speculate about the possibilities; but this is a fact. Surgeons should be aware so that they are not misled by unique British experiences of relatively high rates of surgical infectious complications, outcomes that do not characterize surgical experience in the rest of the developed world.

The Effect of New Monofilament Absorbable Sutures on the Healing of Musculoaponeurotic Incisions, Gastrotomies, and Colonic Anastomoses

Pamela A. Foresman; Richard F. Edlich, MD, PhD; George T. Rodeheaver, PhD

• The purpose of this study was to quantitate the effect of two new synthetic monofilament absorbable sutures, Maxon and PDS, on the healing of musculoaponeurotic incisions, gastrotomies, and colonic anastomoses. Wound healing was assessed by measuring the resistance of the closed wound to leak or burst with controlled infusion of fluid. Bursting strength measurements of these incisions were compared with those undertaken in age-weight matched controls without wounds to determine the rate of gain of wound strength. The bursting strength measurements of unwounded tissue was found to vary according to the age, weight, and specific tissue. As the animals gained weight over 42 days, the bursting strength of their colons and musculoaponeurotic tissues significantly increased. In general, the regain of prewounding bursting strength was inversely proportional to the bursting strength of the unwounded tissue. The bursting strength of abdominal musculoaponeurotic tissue was the highest, followed by the stomach and then the colon. The time intervals in which the wounded musculoaponeurotic tissues, gastrotomies, and colonic anastomoses regained the strength of the unwounded tissue was 42, 14, and 7 days, respectively. The performance of Maxon and PDS sutures in the musculoaponeurotic tissues, gastrotomies, and colonic anastomoses was similar.

(*Arch Surg* 1989;124:708-710)

Polyglycolic acid and polyglactin 910 sutures are used routinely in surgery. These braided sutures degrade in tissue by simple hydrolysis, resulting in a tissue response and absorption rate that is more predictable and reliable than gut sutures.[1,2] Because of the inherent rigidity of polyglycolic acid and polyglactin 910 polymers, monofilament sutures produced from these polymers are stiff and inflexible, precluding their use as a monofilament in sizes larger than 7-0.

An extensive research program has led to the discovery of novel polymers that can be converted into two uniquely flexible monofilament absorbable sutures of all sizes. One monofilament is prepared by polymerizing the monomer, paradioxanone, in the presence of a suitable catalyst to the polymer, polydioxanone (PDS).[3] The other is made from a copolymer of glycolide and trimethylene carbonate (Maxon).[4] Like the braided absorbable sutures, these new monofilament sutures are absorbable by simple hydrolysis with minimal tissue response. However, these monofilament sutures retain their strength for a substantially longer period of time than the braided synthetic absorbable sutures. By 21 days, the braided synthetic absorbable sutures have lost their strength, while the monofilament absorbable sutures still retain 30% to 40% of their initial strength at 42 days after implantation.[3,4]

Their retention of strength for an extended period should permit secure apposition of the divided edges of different incised tissues until the healing wounds can withstand stress without mechanical sutural support. Consequently, the purpose of this study was to determine the relative importance of these new synthetic monofilament absorbable sutures to the strength of healing wounds in various gastrointestinal tissues—musculoaponeurotic incisions, gastrotomies, and colonic anastomoses. The results of this experimental study demonstrate that these monofilament sutures maintain sufficient strength to permit secure repair of these incised tissues in healthy animals.

MATERIALS AND METHODS

Sutures

All sutures were obtained from commercial sources. The size of suture and needle available, respectively, for use on the various wounds were as follows: (1) colon—Maxon, 7-0 and TE-10; PDS, 7-0 and BV-1; (2) stomach—Maxon, 6-0 and TE-10; PDS, 6-0 and C-1; and (3) abdomen—Maxon, 5-0 and TE-1; PDS, 5-0 and RB-1.

Experimental Design

Two hundred male Sprague-Dawley rats, weighing between 225 and 255 g, were used for this study. All animals were assessed for good health during a one-week period before the study as evidenced by a gain in weight. The animals were caged individually and given free access to water and rat chow (Purina 5012). Room conditions were maintained at 23°C ± 1°C and 50% relative humidity, with a 12-hour light/dark cycle. The animals were then randomly assigned into two treatment groups. One group (160 animals) underwent a standardized surgical procedure, while the other group (40 animals) served as the controls. In the surgical group, all animals underwent a colonic anastomosis, closure of a gastrotomy, and closure of the midline abdominal incision. In each animal, the same type of synthetic monofilament absorbable suture was utilized for each surgical procedure. By random assignment, Maxon sutures were utilized in half of the animals, while PDS sutures were used in the remaining animals. Randomly selected groups of control animals and those receiving Maxon or PDS sutures were selected for wound-healing measurements at the following time intervals after surgery: immediately after surgery (0) and at 7, 14, 21, and 42 days. At each time interval, the interrupted suture loops used in wound closure remained intact during the healing measurements in half the animals, while they were cut before the healing measurements were undertaken in the remaining animals. With a dissecting microscope and microsurgical instruments, the suture loops were cut at the knot with as little disturbance of the tissue as possible and left in the tissue.

Surgical Procedure

Each animal fasted for 24 hours before surgery. Anesthesia was accomplished with an intraperitoneal injection of pentobarbital sodium (43 mg/kg). The abdominal hair was clipped with electric clippers and then depilated with a depilatory preparation. After

Accepted for publication Oct 28, 1988.

Bursting strength of wounds was determined at time of surgery (0) and at various periods over 42 days. Bursting strength was determined with sutures intact (solid lines) or sutures cut (dashed lines). Two different suture materials were evaluated—a copolymer of glycolide and trimethylene carbonate (Maxon), solid circles; and polydioxanone (PDS), pluses.

copious rinsing with water, the skin was prepared with an iodophor antiseptic solution and then isolated with sterile drapes for surgery. With aseptic technique, a 5.5-cm midline incision was made through the abdominal skin, beginning 0.5 cm below the xiphoid process. The linea alba and underlying peritoneum were then incised. The length of this incision through this musculoaponeurotic layer and peritoneum was identical to that of the skin.

The site for the left colon anastomosis was identified 2.5 cm above the pelvic floor. The left colon was divided transversely. The anastomosis was accomplished using one layer of interrupted 7-0 synthetic monofilament absorbable sutures spaced approximately 2 mm apart. Eight sutures were used in each anastomosis.

A gastrotomy was then performed in each animal. A 10-mm-long incision was made in the anterior gastric wall in the glandular portion of the stomach. The incision began 10 mm from the pylorus to avoid injury to the antrum and extended 5 to 7 mm from the nonglandular portion (rumen) of the stomach. The gastrotomy was approximated by one layer of interrupted 6-0 synthetic monofilament absorbable sutures spaced about 2 mm apart.

The linea alba was approximated by a one-layer closure with interrupted 5-0 synthetic monofilament absorbable sutures. The distance between the entrance and exits of each interrupted suture and the cut edges of the linea alba was 5 mm. The distance between each interrupted suture loop was also 5 mm. The divided skin edges were apposed by wound closure tapes. Each animal was bandaged with sterile gauze and wrapped in cloth tape. All animals were allowed food and water ad libitum 24 hours after surgery. No postoperative deaths occurred.

Analysis of Healing Strength

Healing strength was defined as the pressure at which leakage or rupture occurred when the tissue was inflated with a constant infusion of water provided by an infusion pump (Harvard). The pressure generated in each test sample was measured by a pressure transducer (Bentley Trantes Model 800). The signal from this transducer was amplified and connected to a calibrated strip chart recorder. At the instant of leakage or rupture, the pressure was recorded for each specimen. The site of rupture (eg, incision or unwounded tissue) was also noted. The weight of each animal was recorded before each wound-healing measurement.

Musculoaponeurotic Tissue

The strength of the abdominal wall was determined by measuring the wound-bursting pressure. The musculoaponeurotic tissue of the abdominal wall was exposed by incising the 5.5-cm-long skin wound and reflecting back the skin. A condom was placed over the tip of a filling catheter, inserted into the peritoneal cavity through a rectal perforation, then passed along the ventral surface of the abdominal cavity until its tip was below the xiphoid. The abdominal cavity was isolated by using strong cotton cords to bind circumferentially the abdomen at the levels of the xiphoid and the pelvic crest. The condom was filled with water at a rate of 35.37 mL/min. Because the condom provided no resistance to distention, all resistance to filling was derived from the musculoaponeurotic tissues. When the abdomen burst, the site of rupture and the bursting pressure were recorded.

Stomach

The entire stomach was removed from the burst abdomen. Because the closed gastrotomy incision was located in the glandular half (corpus) of the stomach, only the glandular part of the

stomach was subjected to the wound-healing measurements. The nonglandular part (rumen) was isolated from the corpus by a circumferential 4-0 silk suture. The filling catheter was inserted through the pylorus into the stomach and secured by another 4-0 silk suture. The corpus with its healing incision was then filled with water at a constant rate of 7.08 mL/min. The pressure and the site at which rupture or leakage occurred were recorded.

Colon

A 5.0-cm segment of the left colon with the anastomosis as its midpoint was excised. The distal end of the transected colon was ligated with a 4-0 silk suture, and the filling catheter was passed into the proximal end and secured by a 4-0 silk suture. The isolated colon was filled with water at a constant rate of 1.79 mL/min until leakage or rupture occurred. The pressure and site at which rupture or leakage occurred were noted.

RESULTS

The animals tolerated the surgical procedure well. They were alert and physically active within three hours of being bandaged. Food was withheld for 24 hours to allow for adequate recovery of basic functions. After being given access to solid food, the animals were excreting solid waste within 48 hours. All animals ate heartily and showed no signs of fever or discomfort.

Efforts were made to standardize the weights of the animals undergoing surgery. Thereafter, the homogeneity of their weights was used as a monitor of well-being. No animals had to be eliminated because of a malfunctioning gastrointestinal tract as determined by subsequent weight loss. All animals steadily gained weight during the study (Table 1). At the end of six weeks, the animals had almost doubled their weight since the time of surgery.

The presence of suture material in the tissue played a variable role in the tissue's ultimate security, depending on the tissue being examined and its rate of healing (Figure). The type of suture material used did not seem to influence the level of wound security or rate of healing. As expected, the security of incised wounds in the colon, stomach, and musculoaponeurotic tissues immediately after surgery was supplied by the interrupted sutures (Tables 2 through 4). When these sutures were cut, no pressure was required to burst these wounds. The rate of wound repair was different in each of the tissues examined. Within one week, the mean burst or leak strength of colonic anastomoses was comparable with that of intact colons, even when the interrupted suture loops were cut. The mean burst or leak strength of gastrotomies with sutures intact was similar to that of the control stomachs within seven days after surgery. The synthetic monofilament sutures in the gastrotomies seven days after surgery obviously contributed to the strength of these wounds as evidenced by the significantly reduced mean burst or leak strength of the gastrotomies after cutting the interrupted suture loops. By 14 days, the mean burst or leak strength of gastrotomy incisions with cut suture loops was comparable with that of the control stomachs.

Sutures played an important role in maintaining the strength of the musculoaponeurotic wounds until 42 days after surgery. At 7, 14, and 21 days after surgery, division of the interrupted suture loops was associated with a significant reduction in the mean burst strength of the musculoaponeurotic wounds. The mean burst strength of incised musculoaponeurotic tissues with intact sutures was comparable with that of the control musculoaponeurotic tissues by 14 days after surgery. Sutures did not contribute to the burst strength of musculoaponeurotic wounds 42 days after surgery as evidenced by the mean burst strength with sutures intact being similar to that of musculoaponeurotic tissues tested with sutures cut. By 42 days after surgery, it seemed that these abdominal wounds had attained their maximum level of healing strength, which was only 83% of the rupture strength of comparable control animals with normal abdominal tissue.

COMMENT

Surgeons should select an appropriate closure technique on the basis of objective data on the biology of wound repair. Information that is useful in making such a decision is the normal strength of tissues, the rate with which wounds gain strength, and the rate at which the wound closure material loses strength in the tissues. The strength of healing incisions may be measured using either a bursting strength technique[5] or a breaking strength technique.[6] The former technique may be more instructive because increased intraluminal pressure plays an important role in anastomotic leakages as well as disruption of abdominal wounds.[7]

The bursting strength of unwounded tissues will vary according to the animal's age, weight, and the specific tissue. As the rats gained weight over the 42 days of observation, the bursting strength of the colon and abdominal musculoaponeurotic tissue significantly increased. Levenson and coworkers[7] demonstrated that the breaking and tensile strength of rat skin increased with age and body weight. Because the animal's weight and age seem to be important determinants of tissue strength, the use of age-weight–matched controls is recommended for experimental studies of wound repair.

Immediately after surgery, the burst or leak strength of all the wounds was low. During this period, wound security depends primarily on the interrupted suture loop, as evidenced by the absence of bursting strength after division of the suture loops. In general, the time required for the tissues to regain maximum strength was inversely proportional to the bursting strength of the unwounded tissue. Thus, abdominal musculoaponeurotic incisions, gastrotomies, and colonic anastomoses regained their maximum strength 42, 14, and 7 days, respectively, following surgery. Once the wounded tissue attained the burst strength of unwounded tissue, the tissues frequently burst at sites other than the wound. This finding suggests that the wounds were stronger than the surrounding unwounded tissue. Although we can see no advantage in the wound being stronger than the unwounded tissue, these findings serve to emphasize that the sutures adequately restored the integrity of the divided tissue. The performance of the two synthetic monofilament sutures in the musculoaponeurotic tissues, colonic anastomoses, and gastrotomies was similar. While our studies provide considerable support for the use of these new absorbable monofilament synthetic sutures in musculoaponeurotic tissue, stomach and colon, we must reiterate that our studies were restricted to healthy animals. The use of these sutures for closure of wounds in animals with impaired healing should be the subject of additional investigations.[8]

THE NATURAL CHOICE

GORE-TEX® SOFT TISSUE PATCH

In reconstructive surgery, a patient's own tissue is not always adequate. However, today surgeons do have alternatives. When a biomaterial is indicated, the GORE-TEX Soft Tissue Patch is the natural choice.

This remarkable sheet of GORE-TEX (expanded polytetrafluoroethylene) is engineered to provide improved performance in a wide range of applications. Since its introduction in 1982, the GORE-TEX Soft Tissue Patch has been used in more than 50,000 clinical cases worldwide.

The GORE-TEX Soft Tissue Patch combines high, balanced strength with softness and conformability. It is easy to shape and contour without fraying. Its microporous structure allows natural tissue ingrowth leading to potential treatability in the presence of infection. Next to delicate internal organs, the GORE-TEX Soft Tissue Patch has shown a significant reduction in adhesion formation and tissue erosion.

The exceptional versatility of the GORE-TEX Soft Tissue Patch makes it the natural choice in a wide range of applications.

- Abdominal Wall Reconstruction
- Hernia Repair
- Thoracic Wall Reconstruction
- Diaphragm Reconstruction
- Rectal and Vaginal Suspension
- Urethral Suspension
- Gastric Banding
- Facial Augmentation and Sling Procedures
- Related Pediatric Reconstructions

Diagnosis and Treatment of Duodenoenteric Fistulas Complicating Crohn's Disease

Kenneth K. W. Lee, MD, Wolfgang H. Schraut, MD

• A duodenoenteric fistula is an unusual complication of Crohn's disease that requires surgical intervention and may present a difficult management problem. Eleven patients with this condition were treated with an ileocolectomy with primary anastomosis and closure of the duodenal defect after takedown of the fistula. In all patients, the duodenal tissues were free of pathologic evidence of Crohn's disease. The fistula was found to result from Crohn's disease limited to the ileocolonic segment or from anastomotic complications in some patients who had previously undergone ileocolonic resections. Satisfactory healing at the ileocolonic anastomosis and at the duodenal closure site occurred in ten patients; breakdown of the duodenal closure leading to sepsis and death occurred in one patient with an unusually large defect in the first portion of the duodenum. In most instances, these fistulas can be treated safely and adequately by resection of the diseased intestinal segment and simple direct duodenal closure. However, safe management of large duodenal defects may require the use of other methods, such as a serosal patch or creation of a duodenojejunostomy.

(*Arch Surg* 1989;124:712-715)

Fistulous communication between the duodenum and the small or large intestine is an unusual condition that may pose challenging problems for the surgeon. Duodenoenteric fistulas most often have been associated with colonic carcinomas near the hepatic flexure, which penetrate into the underlying duodenum and pancreas. Welch and Warshaw[1] have estimated that these malignant fistulas occur in one of 900 carcinomas of the colon. Less commonly, duodenoenteric fistulas have resulted from benign conditions, such as peptic ulcer disease,[2] cholecystitis,[3] duodenal diverticulitis,[4] and appendicitis.[5]

Although internal and external fistulas commonly form in association with Crohn's disease, with some investigators reporting the incidence of fistulous disease to be as high as 60%,[6] duodenoenteric fistulas resulting from Crohn's disease are distinctly uncommon, having been reported, to our knowledge, in fewer than 40 patients.[7-18] Recently, however, we have encountered this disorder with increasing frequency. We therefore undertook a review of our experience with duodenoenteric fistulas associated with Crohn's disease to develop principles for the diagnosis and treatment of this potentially difficult problem.

Accepted for publication Dec 7, 1987.

PATIENTS AND METHODS

The clinical records, operative reports, and pathology reports of all patients undergoing laparotomy for Crohn's disease at The University of Chicago Hospitals and Clinics between 1970 and 1986 were reviewed. This review included 467 patients who had Crohn's ileitis, ileocolitis, or colitis. In 191 (41%) of these patients, internal or external fistulas were present. Eleven patients (2.4%) had a duodenoenteric fistula.

RESULTS

Patient Characteristics

The group of 11 patients consisted of nine men and two women. Their ages ranged from 28 to 74 years (mean, 42.2 years). The diagnosis of Crohn's disease was made five to 32 years before the development or detection of the duodenoenteric fistula. Six of the 11 patients had undergone previous ileoascending colectomies with ileotransverse anastomosis (one at our hospital and five at other institutions) between one and seven years earlier.

Clinical Data

The most common symptoms and signs encountered in evaluating these patients were chronic fatigue, weight loss, abdominal pain, anorexia, and diarrhea. Anemia, intermittent fever, and an abdominal mass were noted in seven patients. Two patients had symptoms consistent with recurrent partial small-bowel obstruction. Feculent emesis, a finding highly suggestive of a duodenocolic fistula, occurred in a single patient; this was the only patient in whom the diagnosis of a duodenoenteric fistula could be made based on the medical history and physical examination.

Diagnostic Studies

All 11 patients underwent preoperative barium contrast studies of the gastrointestinal tract, following which the duodenoenteric fistula was detected in nine of the patients. The examination of the stomach and small bowel demonstrated the fistula in five patients (Figure, left), suggested the presence of a duodenal fistula in five patients, and

Definitive diagnosis of duodenoenteric fistula most often is made by upper or lower gastrointestinal tract contrast roentgenography. The two examinations are complementary, with one examination often yielding normal results and the other demonstrating presence of fistula. Left, Upper gastrointestinal tract roentgenogram showing fistulous tract at junction of second and third portions of duodenum (arrow). Right, Lower gastrointestinal tract roentgenogram showing fistula (arrow), which permits passage of air and contrast material into duodenum.

yielded normal findings in one patient. Barium enema examination demonstrated the fistula in six patients (Figure, right) and was nondiagnostic in the others. The fistula was also seen in the duodenum of one of three patients who underwent preoperative esophagogastroduodenoscopy.

Indications for Surgery and Preoperative Preparation

In the nine patients with roentgenographic evidence of the duodenoenteric fistula, the fistula was an indication for surgery, but in no case was it the sole indication. In all patients, several factors indicated surgery, including recurrent small-bowel obstruction; failure of medical management to halt weight loss, abolish abdominal pain, and control severe diarrhea; enterocutaneous fistulas; and septic complications, such as an abdominal mass/abscess with recurring fever. Two patients received total parenteral nutrition for six and 16 months, respectively, before surgery. Although symptoms such as feculent emesis and abdominal pain resolved, the fistula did not close in either patient. In six other patients, a short course (two to four weeks) of total parenteral nutrition similarly improved the general state of health but did not cause closure of the fistula. In the immediate preoperative period, all patients underwent thorough mechanical bowel preparation (gut lavage with oral electrolyte solution, enemas). Perioperative antibiotic therapy (parenterally administered broad-spectrum cephalosporins) was given to all patients.

Surgical Findings and Procedures

At operation, the precise pathologic anatomy of the duodenoenteric fistula was determined. In four of the six patients who had undergone previous ileocolectomy, the fistula was found to communicate between the site of anastomosis and the duodenum. In two of these four patients, active Crohn's disease was present at the site of the previous ileocolonic anastomosis; in the other two, there was no evidence of active Crohn's disease at the previous anastomotic site, and the fistulas were probably the result of anastomotic complications, such as formation of a perianastomotic abscess or leakage. In the remaining two patients who had undergone previous ileocolonic resection, the fistulous tract was found to arise from the preanastomotic area harboring recurrent Crohn's disease.

Among the five patients who had not undergone previous intestinal resections, the anatomy of the fistulous communication was more variable. In one patient, two fistulas were found between the transverse colon and the first and second portions of the duodenum. In two patients, the fistulas connected the cecum or proximal transverse colon with the first or second portion of the duodenum. In another patient, the fistulous tract extended from the transverse colon through the mesocolon into the third portion of the duodenum and the pancreas. In the fifth patient, the fistula arose in the distal transverse colon and communicated with the fourth portion of the duodenum at the ligament of Treitz. Although an active inflammatory response at the site of the duodenal fistula and in the surrounding tissues, including the pancreas, was encountered in all patients, none had evidence of Crohn's duodenitis or gastritis.

A wide range of pathologic abnormalities was found in addition to the duodenoenteric fistulas, including mesenteric abscesses and a variety of other fistulas, such as enteroenteric, enterocolonic, enterocutaneous, colocolonic,

and colocutaneous fistulas, and one particularly tortuous cologastropleurocutaneous fistula.

For all 11 patients, surgery consisted of ileocolonic resection to macroscopically uninvolved margins, takedown of the fistula from the duodenum, and primary repair of the duodenal defect. This was followed by primary ileocolonic anastomosis in ten patients. Total abdominal colectomy with an end ileostomy and a mucous fistula was performed in one patient because of severe pancolitis and active perineal disease. In the six patients who had undergone previous resections, the site of the existing intestinal anastomosis was included in the new resection. In one patient, a coexisting gastropancreatopleurocutaneous fistula, which had developed after a vagotomy and antrectomy performed six years earlier, required distal pancreatectomy, splenectomy, and closure of the gastric defect.

In all 11 patients, the duodenal site of the fistula was treated by débridement of this site and simple closure of the resulting duodenal defect. A nearly circumferential end-to-end anastomosis of the duodenum was necessary in one patient. The duodenal closure was protected with an omental patch in three patients in whom a remnant of the omentum remained. Temporary decompression of the duodenum was achieved by passage of a nasogastric, gastrostomy, or jejunostomy tube into the duodenum.

Complications arose in two patients—one of these patients, in whom a mesenteric abscess had been encountered and drained in the initial surgical procedure, required reexploration on the tenth postoperative day for drainage of a subfascial intra-abdominal abscess. The duodenal closure was intact, and the patient recovered uneventfully. In the second patient in whom simple closure of a 3.5-cm defect in the anterior wall of the first portion of the duodenum was undertaken, a leak developed in this closure. After a prolonged hospital course marked by recurrent sepsis, recurrent leakage, and intra-abdominal bleeding that required two additional laparotomies, the patient died of sepsis. The ten surviving patients have now been followed up for periods ranging from one to nine years. Recurrent active Crohn's disease has been diagnosed in four patients, but in none of these has a recurrence of the duodenoenteric fistula been diagnosed, nor have any of these patients developed duodenal Crohn's disease.

COMMENT

As this article demonstrates, the unusual finding of fistulous communication between the duodenum and the small or large intestine as a complication of Crohn's disease characteristically results from enterocolonic, rather than duodenal, involvement by Crohn's disease. This was the finding in other reports of duodenoenteric fistulas associated with Crohn's disease and in reports of duodenal Crohn's disease. Although Crohn's duodenitis may coexist with Crohn's enterocolitis in patients with such fistulas, fistulas resulting from isolated duodenal disease are extremely rare. Abnormalities of the duodenum, which are detected roentgenographically or endoscopically in patients with duodenoenteric fistulas, most commonly arise secondary to the fistula itself and are nonspecific (non–Crohn's disease) inflammatory changes, that resolve following adequate treatment of the fistula (ie, resection of the primarily diseased bowel, which gives rise to the fistula).

The proximity of the second and third portions of the duodenum to the proximal transverse colon facilitates fistulous communication between these regions, particularly in the setting of Crohn's colitis. However, the first portion of the duodenum and other portions of the intestine also may be involved. The position of the fourth portion of the duodenum at the root of the small-bowel mesentery makes fistulization to this area less likely, but it is possible, as was seen in one of our patients.

In patients who have undergone previous ileocolonic resection with ileoascending or ileotransverse colostomy, the region of the anastomosis is a common site of origin for a duodenoenteric fistula. In this series, the duodenoenteric fistulas in four of the six patients who had undergone such resections arose from the earlier anastomosis. Wilk et al[13] similarly found three patients who had undergone previous ileal resections and ileotransverse colostomies and who had fistulous communication between the perianastomotic region and the duodenum. The ileocolonic anastomosis following ileocolonic resection often is in proximity to the duodenum. As recurrence of Crohn's disease is likely to occur in the preanastomotic ileum, the frequency of duodenoenteric fistulas that arise from the perianastomotic region is not surprising. If one implicates technical factors in the development of these fistulas, as may have been true for two patients in this series, then fistulous involvement of the anastomosis is to be expected. When the existing disease permits, more limited colonic resection with anastomosis to the proximal ascending colon, rather than to distal ascending or proximal transverse colon, may place the subsequent ileocolonic anastomosis further from the duodenum and thereby reduce the risk of a fistula arising between the duodenum and the anastomotic site. Placement of omentum between the anastomosis and the duodenum at the time of the ileocolectomy also may reduce the likelihood that such a fistula will develop.

To our knowledge, no association exists between the risk of developing a duodenoenteric fistula and either the patient's age or the length of the interval since the onset of symptoms of Crohn's disease. A duodenoenteric fistula has been found as little as one year after the onset of symptoms.[8] For reasons that are not clear, there is a marked male preponderance in this series and among other reported cases (28:10) of duodenoenteric fistulas secondary to Crohn's disease.

In the surgical management of a fistulous communication between the duodenum and the small or large bowel involved by Crohn's disease, the surgeon must be aware of the condition of the bowel at both ends of the fistula. Although duodenoenteric fistulas resulting from duodenal Crohn's disease are extremely rare, it is advisable to exclude the presence of Crohn's duodenitis in these patients when it is known preoperatively that the fistula exists. If the duodenal mucosa is normal (with the exception of local inflammatory changes at the fistula site), then the fistula can be disconnected, the diseased ileocolonic segment resected with reanastomosis, and the duodenal defect closed by simple suture after excision of the margins back to normal tissue. In three of our patients, the duodenal defect was found near the pancreatic border and required dissection of the pancreas from the duodenum to allow a secure closure of the duodenal defect. In these situations, meticulous hemostasis and diligent dissection are necessary to prevent injury to the pancreas.

Although the value of an omental or peritoneal patch to buttress the duodenal closure has not been proved scientifically, this is a simple maneuver that may protect the duodenal closure and that is incorporated easily in the repair of the duodenal defect. If the retroperitoneum is markedly inflamed and is the site of an abscess or phlegmon, then vigorous débridement is strongly recommended before the anastomotic suture line is placed in the retroperitoneal bed. Closure of the duodenal defect by a duodenojejunostomy, as advocated by Wilk et al,[13] is not

necessary as a routine procedure. Furthermore, a duodenojejunostomy bypasses a portion of the small bowel; in a patient with Crohn's disease who has undergone previous small-bowel resections, the nutritional consequences of rendering a segment of the remaining small bowel nonfunctional may be substantial. However, in the presence of a large duodenal defect that cannot be closed simply, creation of a duodenojejunostomy or use of a serosal patch may be necessary. This approach might have secured the closure of the large duodenal defect and prevented its leakage in one of our patients. If Crohn's disease should arise in the small-bowel segment used for the serosal patch, however, the duodenal fistula may recur.

We have abstained from placing a drain in the area of the duodenal closure but routinely have inserted an intraluminal tube into the duodenum for decompression either by a gastrostomy or a jejunostomy. At present, we prefer the transgastric placement of such a duodenal tube. This tube is placed across the duodenal closure and allows for enteral alimentation if the duodenal closure should remain edematous and temporarily obstruct gastric emptying during the early postoperative course.

The bowel involved by Crohn's disease is treated according to established guidelines. The extent of the bowel resection and decisions for or against primary anastomosis and primary wound closure must be made on an individual basis, as dictated by the degree of intra-abdominal contamination.

Necrotizing Enterocolitis in Full-term Infants: A Case-Control Study

LTC Thomas E. Wiswell, MC, USA; CPT Carol F. Robertson, MC, USA;
CPT Timothy A. Jones, MC, USA; Capt Deborah J. Tuttle, MC, USAF

We performed a case-control investigation of 43 full-term infants with necrotizing enterocolitis (NEC) to identify possible risk factors and unique features of the disorder in the more mature infant. Two control groups were used. The first consisted of "healthy" term infants. The second was a group of "sick" term infants who did not develop NEC. The 43 term infants with NEC represented 12.7% of all 338 neonates with NEC. The median age at onset of symptoms was 2 days, and 18 infants developed NEC on the first day of life. Two (4.7%) of the 43 affected term infants died, while 35 (11.9%) of 295 preterm infants with the disorder died. Only three of the full-term infants who subsequently developed NEC had entirely unremarkable courses prior to the onset of symptoms. Sick infants, in particular those who are small for gestational age or require exchange transfusions, are at risk for NEC. Several other features that may be associated with the subsequent development of NEC include the following: perinatal asphyxia, presence of umbilical catheters, antecedent respiratory distress, polycythemia, and maternal preeclampsia. Full-term infants with these features should be treated with cautious observation and aggressive management early in the neonatal period should they develop signs and symptoms suggestive of NEC (*AJDC* 1988;142:532-535).

CRITICARE HN®

Because patients with impaired digestion and absorption are often those who need essential nutrients most.

The *only* complete, high-nitrogen elemental diet in a commercially sterile, ready-to-use form.

Dietitians told us that they needed a highly specific nutritional formulation in sterile, ready-to-use form to rapidly renourish their malnourished patients and a product which minimized the risks associated with prepared powdered formulas.

Criticare HN was formulated in response to that need. Developed to provide patients, even those suffering from problems of maldigestion or malabsorption, with the elemental nutrition they so critically need.

Formulated to provide generous levels of the preferred elemental protein for these patients, Criticare HN offers 50% free amino acids and 50% small peptides. Plus 100% of U.S. RDAs for vitamins and minerals in 2000 Calories.

Criticare HN. For stressed patients, it's just what the dietitian ordered.

The complete line of clinically validated, exceptionally well-tolerated adult enteral nutritionals.

This important product is part of what we believe to be one of the broadest lines of technologically advanced, lactose-free enteral nutritionals. Each product is formulated with the precise nutrient values you demand and the exceptional patient tolerance you expect.

75 YEARS OF CATERING TO YOUR PATIENTS' NUTRITIONAL NEEDS.

Excision of the Burn Wound in Patients With Large Burns

William F. McManus, MD; Arthur D. Mason, Jr, MD; Basil A. Pruitt, Jr, MD

• The known major determinants of survival for patients with burn injury are age, burn size, inhalation injury, and infection. The clinical courses of 210 patients with burns of 30% of the body surface or greater treated from Jan 1, 1983, through Dec 31, 1985, were reviewed to determine whether excision of the burn wound could be identified as a factor in survival after massive burn injury. The predominant site of infection changed from the burn wound to the lung, with pneumonia being the most common bacterial infection in patients whose wounds were treated as described. Effective topical control of bacterial proliferation and excision of the burn wound have resulted in replacement of invasive bacterial wound infection by nonbacterial burn wound infection. The apparent advantages of excision, particularly in large burns, may reflect only patient selection, since only those patients who are considered to be physiologically stable and able to tolerate the physiologic stress of excision are considered for operation.

(*Arch Surg* 1989;124:718-720)

The known major determinants of survival for patients with burn injury are age, burn size, inhalation injury, and infection. In light of the current enthusiasm for early excision of the burn wound and reports of general improvement in outcome after burn injury, we reviewed our recent results of care of patients with massive burn injury to evaluate the applicability of excision in such patients.

PATIENTS AND METHODS

The hospital records of 571 burned patients admitted to the US Army Institute of Surgical Research, Fort Sam Houston, Tex, between Jan 1, 1983, and Dec 31, 1985, were reviewed. Of these patients, 474 were male, reflecting the preponderance of male admissions to this center. The ages of this group of patients ranged from 2 months to 97 years, and 62% were admitted to the burn center within 24 hours of injury. Two hundred ten patients (37%) were identified as having massive burn injury, which for this review was defined as involvement of 30% or more of the body surface. The clinical courses of those 210 patients were reviewed.

RESULTS

Among the 210 patients who met the arbitrary definition of massive burn injury, 186 were male and 24 were female. Age ranged from 8 months to 93 years, with a mean of 35.7 years. The mean burn size in this subset was 52.6% of the total body surface, with an average of 32.6% of the surface involved in full-thickness injury. A diagnosis of inhalation injury, established by history, physical examination, fiberoptic bronchoscopy, and xenon 133 ventilation perfusion scan, was made in 118 (56%) of these patients.

One hundred seventeen patients (55.7%) survived. The mean age of surviving patients was 27.9 years, and the mean burn size was 44.5% of the body surface, with a mean of 21.1% full-thickness injury. Inhalation injury was present in 39 surviving patients 33.3%. Excision of the burn wound was carried out in 104 of these 117 patients; the remaining 13 patients had partial-thickness injury that healed spontaneously, without any necessity for excision or autografting of their wounds. Tangential excision of the burn wound, excision to a level within subcutaneous fatty tissue, and excision to the level of the investing fascia were performed as necessary to remove nonviable tissue. The average time to initial excision in surviving patients was 13.5 days after injury (range, fourth to the 31st postinjury day). Those patients undergoing wound excision later in their burn course characteristically had extensive burns with a limited area of full-thickness injury that was excised after spontaneous reepithelialization of the large areas of partial-thickness injury.

Ninety-three (44.3%) of the 210 patients died. The average age among patients who died was 45.1 years, and their mean burn size was 61.9% of the body surface, with an average of 46.6% of the surface involved in full-thickness injury. Seventy-nine (85%) of the patients who died had inhalation injury. Excision of the burn wound was deemed possible in only 40 (43%) of the nonsurviving patients, with the average time to initial excision being 12.5 days after injury. The day of initial excision in this group ranged from the fifth to the 23rd postburn day. The predominant

contraindication to excision of the burn wound in this group was pulmonary insufficiency. The complications of inhalation injury and/or pneumonia necessitating maximal ventilatory support either precluded safe transport of the patient to the operating room or reduced to an unacceptable level the assessed ability of the patient to tolerate the physiologic stress of excision. In some patients renal failure, hemodynamic instability secondary to sepsis, or serum electrolyte derangements precluded or delayed burn wound excision.

Infection was the cause of death in 71 (76.3%) of these 93 nonsurviving patients. Pneumonia was the single most common infection and was identified as a cause of death in 54 patients. Invasive burn wound infection was identified in 24 of the patients who died. Bacterial wound infection occurred in only six patients, while yeast or fungal burn wound infection was identified in 18 of the 24 patients with histologically documented invasive burn wound infection. Causes of death other than infection identified in 22 patients included severe inhalation injury in 12, acute myocardial infarction in five, and pulmonary embolism, resuscitation failure, phenol toxic reaction, aspiration due to a tracheoesophageal fistula, and cerebral edema secondary to hypoxia in one patient each.

COMMENT

Various investigators have reported the consequences of early burn wound excision.[1-3] Among these reports, only one[1] claimed that excision improved the survival of burned patients. In that study, however, there were no controls, the study spanned a period of approximately 45 years during which there was a general improvement in survival after burn injury not necessarily attributable to excision, and most of the described patients had burns of 20% of the body surface or less. Another study[2] reported the results of early excision in patients with burns of 20% to 40% of the body surface and identified no survival advantage. A third article[3] reported on a controlled study in which there was no survival advantage of early excision of burns that exceeded 15% of the body surface. When one compares reported outcomes, comparable populations must be used for such analysis, with particular attention paid to the distribution of inhalation injury and pneumonia within the populations. If excision of the burn wound is to be cited as the reason for improved survival, concurrent controls must be included to validate that conclusion, since without such controls, improvement in survival may merely reflect unintentional selection of patients without inhalation injury or life-threatening infection.

The Figure displays the plane describing the improvement in survival of patients treated at this burn center over the past three decades. The plane was generated by subtracting the calculated death rate, corrected for burn size and age, of patients treated during the years 1980 through 1984 from the similar death rate of patients treated during the period 1950 through 1963. The improvement in survival is indicated on the vertical axis in terms of percentage difference at any combination of burn size and age. The control of burn wound infection is, in part, responsible for the improvement in survival, but to what degree excision of the burn wound is related to the reduction of wound infection is difficult to document.

As previously reported from this institute,[4] inhalation injury alone is associated with a maximum added mortality of 20%, related to burn size and age. Pneumonia is associated with a maximum added mortality of 40%, and the combination of inhalation injury and pneumonia, which are significant independent and additive comorbid factors,

Difference in deaths per 100 patients (1950 to 1963 minus 1980 to 1984) by patient age and burn size.

is associated with a maximum added mortality of 60%, related to burn size and age.

The effects of age and burn size on mortality are given in Table 1. As anticipated, mortality in these 210 patients increased, in general, as either age or burn size increased. The high mortality in the pediatric patients with burns of 30% to 50% of the body surface was anticipated because of the high burn-related mortality in the extremely young. The mean age of the nonsurvivors in that group was 18.8 months, and all were less than 33 months of age.

The generally accepted indications for excision of the burn wound include full-thickness burns of limited extent, deep dermal dorsal hand burns when the total burn is of limited extent, débridement and definitive treatment of high-voltage electric injury, and removal of areas of burn wound infection. The advantages of excision and closure of the burn wound include reduction in the time during which the patient is at risk of invasive burn wound infection and reduction in the magnitude and duration of burn size–related physiologic stress.

These indications and advantages must be balanced against the associated blood loss, which has been estimated to be as high as 9% of the blood volume for each 1% of the body surface excised by tangential technique,[5] the risk of hepatitis and acquired immunodeficiency syndrome after the administration of blood and blood products, and the uncertainty of graft take on subcutaneous fat. Additionally, excision at the levels below the dermis results in loss of viable skin in those areas of partial-thickness injury interspersed with areas of full-thickness injury, thus compounding the donor-recipient site disparity in a patient with extensive burn injury.

Table 2 demonstrates that in these 210 patients there was a marked difference between surviving and nonsurviving patients with massive burn injury in terms of age, total burn size, extent of full-thickness burn, and the presence of inhalation injury.

Table 3 identifies the conditions that precluded operation in the 53 nonsurviving patients whose burns were not excised. Pulmonary insufficiency prevented excision in 43 patients. Inhalation injury and/or pneumonia commonly requiring maximum ventilator settings for ventilatory support were the common causes of pulmonary insufficiency. Hemodynamic instability with or without sepsis and commonly requiring pharmacologic support was the other principal cause of deferring excision (ten patients).

CONCLUSIONS

Apparent advantages of excision, particularly in patients with massive burns, may reflect only patient selection, since complications of the injury per se or of treatment resulted in 57% of the nonsurvivors vs 11% of the survivors being considered too unstable or unable to tolerate excision. Age, burn size, inhalation injury, and infection were, as anticipated, the principal determinants of mortality in this group of patients. The preponderant site of infection, the burn wound in earlier years, is now the lung, and pneumonia is presently the most frequently occurring bacterial infection in massively burned patients. Current techniques of wound care employing topical chemotherapy and, when feasible, excision of the burn wound have reduced the occurrence of invasive burn wound infection. Associated with the decrease in invasive bacterial burn wound infection has been a relative increase in nonbacterial, predominantly fungal, burn wound infection.

ARCHIVES OF INTERNAL MEDICINE

Primary Hyperparathyroidism: A Review of the Long-term Surgical and Nonsurgical Morbidities as a Basis for a Rational Approach to Treatment

Fred W. Lafferty, MD, Charles A. Hubay, MD

We studied long-term morbidity after parathyroid surgery for primary hyperparathyroidism in 100 patients and compared it with the long-term morbidity of medical follow-up from the literature. The surgical treatment of primary hyperparathyroidism was associated with negative results of neck explorations, persistent hypercalcemia, recurrent hypercalcemia, permanent hypoparathyroidism, or recurrent laryngeal nerve damage in 13 (19%) of 68 patients followed up for five years postoperatively. A review of medical follow-up as reported in the literature showed progression of disease in 8% to 22% of patients followed up for five to ten years. There was no convincing evidence that mild primary hyperparathyroidism resulted in progressive osteoporosis or renal failure. Furthermore, no significant improvement in hypertension, peptic ulcer disease, or renal function followed successful parathyroid surgery. Unless future studies demonstrate progressive osteoporosis or renal damage in untreated, mild primary hyperparathyroidism, medical follow-up is a reasonable alternative to surgery in the compliant patient over 50 years of age. (*Arch Intern Med.* 1989; 149:789-796).

Diagnostic Pneumoperitoneum in the Pediatric Patient With a Unilateral Inguinal Hernia

Gregory A. Timberlake, MD; M. Gage Ochsner, MD; Randall W. Powell, MD

• Controversy continues among surgeons over the management of pediatric patients with unilateral groin hernias. Currently, advocated treatment modalities include repair of only the clinically apparent side, exploration of the contralateral side when the ipsilateral hernia is repaired, or performance of contrast herniography before surgery. Another technique for consideration—diagnostic intraoperative pneumoperitoneum—is a simple, quick, safe, and highly accurate means of detecting a clinically inapparent contralateral inguinal hernia during the initial surgery. This technique, the results of its use, and a review of the literature are included.

(*Arch Surg* 1989;124:721-723)

Controversy continues to provoke interest among surgeons concerning management of pediatric patients with unilateral inguinal hernias. Many methods of handling the asymtomatic contralateral groin have been advocated. The treatment modalities currently recommended include (1) repair of the clinically apparent hernia only, (2) exploration of the contralateral side when the clinically apparent hernia is repaired, or (3) performance of contrast herniography before surgery, with repair of both sides if the herniogram is abnormal.

At the US Naval Hospital, San Diego, we have used intraoperative diagnostic pneumoperitoneum to evaluate the contralateral groin for hernia, which has proved to be a safe, quick, humane, economical, and logical approach to the problem. It avoids "unnecessary" surgery in the guise of asymptomatic groin explorations and permits "necessary" surgery for repair of a contralateral inguinal hernia to be performed while the patient is under the same anesthetic. Our report describes the technique used and the results of inguinal hernia repair in infants, children, and adolescents over a six-year period and compares this technique to others in the literature.

PATIENTS AND METHODS

The medical records of all 552 infants, children, and adolescents undergoing repair of an inguinal hernia or communicating hydrocele for the six-year period from Oct 1, 1978, through July 5, 1984, were examined for age, sex, presenting complaint, history of previous surgery, preoperative physical findings, findings at operation, results of diagnostic pneumoperitoneum (if performed), and operative complications. Informed consent for the operative procedure was obtained from the patients' parents. All of the operations were performed by, or under the supervision of, a pediatric surgeon (R.W.P.).

Repair of the indirect inguinal hernia or communicating hydrocele was by high ligation with excision of the sac. The four direct inguinal hernias and two femoral hernias were repaired with a standard Cooper's ligament herniorrhaphy.

All patients underwent diagnostic pneumoperitoneum except those who had previously undergone surgery on the contralateral side, those with bilateral inguinal hernias or hydroceles on presentation, or those in whom the procedure was not technically possible. Also excluded were those patients with an intra-abdominal foreign body, such as ventriculoperitoneal or peritoneovenous shunts. All operations were performed under general anesthesia with endotracheal intubation. The technique, as previously described from our institution,[1] required the isolation and opening of the hernia or hydrocele sac and introduction of a small, 10- to 14-F Robinson catheter through the neck of the sac and into the peritoneal cavity. The peritoneal cavity was insufflated with room air using a bulb syringe until moderate abdominal distention was obtained, as judged on physical examination by the presence of tympany over the liver. The contralateral groin was then palpated for pneumotosis, and in males the scrotum was also palpated. The presence of crepitus in the groin or scrotum constituted an abnormal test finding; we performed exploration of that groin after the insufflated air was evacuated from the peritoneal cavity and the ipsilateral hernia or hydrocele was repaired.

RESULTS

Over the three-year review period, 552 infants, children, and adolescents (426 boys and 126 girls) underwent repair of inguinal hernias or hydroceles. Diagnostic pneumoperitoneum was not attempted in 172 patients. Fifty-six of these 172 patients had bilateral hernias or hydroceles, 30 of 172 patients had undergone previous surgery for a contralateral hernia or hydrocele, and four patients had a ventriculoperitoneal shunt in place. In the remaining patients, diagnostic pneumoperitoneum was not attempted, either because of older age or because permission to perform the procedure was not obtained from the parents before surgery.

Diagnostic pneumoperitoneum was attempted in 380 patients (291 boys and 89 girls). In 41 of the boys, the catheter could not be passed into the peritoneal cavity because of a narrow-necked hernia or hydrocele sac. In the remaining 339 patients (250 boys and 89 girls), intraoperative diagnostic pneumoperitoneum was performed satisfactorily. The data (Table 1) show that in boys having a right inguinal hernia or hydrocele, an associated diagnostic pneumoperitoneum and groin exploration that gave abnormal results were present in 19% (40/210) in whom the procedure was successfully performed. Similarly, a left inguinal hernia or hydrocele was associated with abnormal contralateral findings for 26% (21/81) of the boys. In the girls (Table 1), a right inguinal hernia was associated with a pneumoperitoneum and exploration that gave abnormal results for 31%, and a left inguinal hernia was associated with a pneumoperitoneum and exploration that gave abnormal results for 30%.

Almost one third of our patients were 1 day to 6 months old, 46% of whom had bilateral inguinal hernias on either initial physical examination or diagnostic pneumoperitoneum. The incidence of bilaterality then decreased steadily with age, although our data for those children older than 6 years may be biased or distorted. Diagnostic pneumoperitoneum was not always performed on children having a larger body size because of the difficulty in performing an adequate pneumoperitoneum.

Table 2.—Complications Noted in Patients With Hernias

Patient Group	No. (%)
All patients (n = 552)	
Emesis after surgery	1 (0.2)
Apnea after surgery	1 (0.2)
Shoulder pain	1 (0.2)
Injury to vas deferens	4 (0.7)
Infection	2 (0.4)
Scrotal hematoma	4 (0.7)
Patients undergoing pneumoperitoneum (n = 380)	
Shoulder pain	1 (0.3)
Injury to vas deferens	1 (0.3)
Infection	1 (0.3)
Scrotal hematoma	2 (0.5)
Technical failure (inability to pass catheter)	21 (10.8)

To date, in follow-up of one to eight years, there have been 15 (8.7%) occurrences of symptomatic contralateral inguinal hernias in the 172 patients who did not undergo diagnostic pneumoperitoneum. In those who successfully underwent diagnostic pneumoperitoneum (339 patients), there were no false-positive results found at exploration. To date, three patients (0.9%) have had a clinically apparent hernia in the contralateral groin.

For the entire study group, there was a 2.54% complication rate. None of these complications occurred in patients in whom diagnostic pneumoperitoneum was attempted. There was a technical failure rate of 10.8% in the diagnostic pneumoperitoneum group because of an inability to pass the catheter through a narrow-necked sac. The various complications encountered are shown in Table 2.

COMMENT

The question of whether to explore the contralateral asymptomatic groin when a pediatric patient has a unilateral inguinal hernia has provoked much controversy among surgeons primarily due to the high incidence of a contralateral patent processus vaginalis in pediatric patients with inguinal hernias. Snyder and Greaney,[2] quoting autopsy studies by Sachs, Campers, and Engel, reported that at birth 80% to 94% of all neonates will have an open processus, and at 1 year of age as many as 57% of these processuses will still be patent. While the presence of a patent processus vaginalis may not constitute a hernia, as noted by Holder and Ashcraft,[3] an indirect inguinal hernia will not be clinically apparent unless a patent processus is present. In this regard, Rowe et al,[4,5] in a study of 2764 patients, showed that in an infant with a unilateral groin hernia, the contralateral processus vaginalis obliterates in only 60% of the patients by 2 years of age. In the remaining 40% of the patients, the processus remains open; in half of these patients a clinical hernia will develop. Many other studies have provided data that tend to support the high incidence of asymptomatic contralateral patent processus vaginalis or inguinal hernia in children. For example, studies in which routine contralateral groin explorations were performed indicated 40% to 74% of the patients had a patent processus vaginalis or a hernia.[3-9] Other studies, in which only the symptomatic side was repaired and patients were followed up for the occurrence of a contralateral groin hernia, reported that as many as 31% of these patients would have a groin hernia in the side not operated on.[7,8,10-12]

There are three common modes for evaluating the asymptomatic contralateral groin as follows: (1) repair of the symptomatic side only with close follow-up, (2) exploration of the contralateral side in conjunction with repair of the ipsilateral side, and (3) use of preoperative contrast herniography to assess the contralateral side for the presence of a patent processus vaginalis. A fourth method has been described as transperitoneal probing of the contralateral groin with a Bakkes dilator or other instrument at the time of ipsilateral hernia repair.[13] However, because of a high false-negative rate,[11] it has never been widely accepted.

Many surgeons advocate the repair of only the symptomatic inguinal hernia, with repair of the contralateral side only if a hernia develops.[2,10-12] These surgeons believe routine bilateral exploration should not be performed because of the high number of unnecessary procedures that would be performed, exposure of the patient to increased anesthesia time, and the increased possibility of major complications (testicular atrophy or injury to the vas deferens). The disadvantage of this approach is that a number of necessary procedures are not performed at the initial operation; thus, the child is exposed to the risk of undergoing a second anesthetizing and operation.

Other surgeons advocate routine exploration of the asymptomatic contralateral groin when the clinically apparent hernia is repaired.[3-9] The advantage of this technique is that the second hernia is detected and repaired at the initial operation, thus sparing up to 30% of the patients from the risks of a second anesthetizing and surgery. The disadvantages of this technique are that in a substantial number of patients (increasing with patient age), the exploration does not disclose an abnormality; thus, the patients have had an unnecessary inguinal incision, they undergo anesthesia longer, and, in male patients, there is a risk of injury to cord structures and testicular atrophy. Bock and Sobye[10] reported the latter two complications occurred in 1% to 13% of male patients.

Because of the problems with both of these treatment modalities, many surgeons and radiologists have enthusiastically endorsed preoperative inguinal herniography.[3,14-23] In 1967, Ducharme et al[16] first reported this technique, which utilizes the intraperitoneal injection of a water-soluble contrast agent to radiographically define pathologic lesions of the inguinal canal. Since then, this technique has been used in thousands of patients, with a 95% to 99.5% accuracy rate[15,17,19-22] and a false-negative rate of 0.5% to 4.0%, if patients with unexplored contralateral groins are followed up closely.[19,20,22] Disadvantages of this technique include the discomfort of the procedure to patients, exposure to radiation, time and expense, rare false-negative results, and a complication rate of up to 11%.[14,17-19] These

complications are usually reported as minor and include fever, sweating, nausea and vomiting, and abdominal pain.[14,15,17-19] Ducharme et al[24] have recently reported two serious complications of herniography—intestinal obstruction due to a bowel hematoma and cellulitis of the abdominal wall resulting in septicemia and skin slough that requires skin grafting. Because of these two cases and a similar case reported by Butsch and Kuhn,[25] Ducharme et al have critically reexamined their indications for inguinal herniography. They now state inguinal herniography should no longer be used to rule out a hernia, to detect the presence of a contralateral sac, or to confirm the presence of a communicating hydrocele because of the risks of these rare but life-threatening complications.[24]

As noted by White et al, if a method were developed that avoided asymptomatic groin explorations, "there would appear to be few if any objections to closing a contralateral peritoneal sac at the time a unilateral hernia was repaired."[22(p825)] Intraoperative diagnostic pneumoperitoneum seems to be such a method. In this series, no false-positive results have been noted to date in those patients who successfully underwent the procedure. There have been only three false-negative results (0.9%) found in our limited follow-up. Of course, the true false-negative rate cannot be ascertained from our data because routine contralateral explorations were not done. We are convinced, however, that if the contralateral groins had been explored, few hernias would have been found.

There have been no complications related to the procedure itself, including no instances of respiratory compromise or air embolism. Because of our concern that respiratory compromise could result from the distention of the peritoneal cavity by the insufflated air, we advocate performing the technique only under general anesthesia with endotracheal intubation. We do not believe that use of mask general anesthesia, local anesthesia, or regional anesthesia is appropriate when diagnostic pneumoperitoneum is performed. We also attempt to evacuate all of the insufflated air possible before removal of the Robinson catheter and repair of the ipsilateral hernia sac. Another theoretical concern, not encountered in this series, is the risk of air embolism. We believe this risk is low and have continued to use manual insufflation with room air, as described. The use of an automatic insufflator and carbon dioxide gas in an attempt to better quantitate the degree of pneumoperitoneum and reduce the risk of air embolus, however, would be reasonable. Additionally, we do not perform the test in children with intra-abdominal foreign bodies, such as ventriculoperitoneal or peritoneovenous shunts, because of the risk of air embolism through the shunt tubing.

We were concerned about the technical failure rate of 10.8% because of our inability to pass a 10- to 14-F Robinson catheter through the neck of the hernia sac. This problem occurred only in male patients and was always a result of the narrowing in the sac at the internal ring. The frequency of this problem was equal among those with hernias and communicating hydroceles. This problem could conceivably be corrected by the use of a smaller catheter.

Scant attention has been given to this procedure in the literature. In 1924, Farr[26] first described the use of pneumoperitoneum in the preoperative diagnosis of inguinal hernia. Arner and Fernstrom[27] reported the use of this procedure in the preoperative diagnosis of clinically uncertain inguinal hernias. In 1953, Shiozaki et al[28] reported the use of intraoperative diagnostic pneumoperitoneum in 49 patients with no complications and an 83.7% accuracy rate. Bulow[29] described 117 patients studied with this technique in 1974. In 14% of the patients, a contralateral hernia was demonstrated with no false-positive results and one false-negative result. The only complication noted was one case of localized subcutaneous emphysema that resolved spontaneously. Singh et al[30] performed a prospective evaluation of preoperative pneumoperitoneum with preoperative inguinal herniorrhaphy. They found that pneumoperitoneum was more reliable than inguinal herniography, having an accuracy rate of 98.4%, fewer complications, and fewer technical failures.

Prostaglandin E_2 in Pyloric Stenosis

Gideon Goldman, MD; Elsa Tiomny, MD; Perry J. Kahn, MD; Dalia Somjen, PhD; Zamir Halpern, MD; Tuvia Gilat, MD; Theodor Wiznitzer, MD

• Prostaglandins are presumed to have many cytoprotective properties that play a role in the pathogenesis of duodenal ulcer and its complications where decreased levels of prostaglandin E_2 (PGE_2) impair gastric motility, oppose ionic membrane influx, and enhance obstructive changes. These are just some of the mechanisms that may cause pyloric obstruction and may result from decreased PGE_2 levels. To evaluate this hypothesis, 17 patients with duodenal ulcer complicated by pyloric stenosis were examined. Biopsy specimens were obtained from the duodenal bulb, ulcer margins, gastric antrum, fundus, and gastric secretions. Prostaglandin E_2 levels were measured and compared with those taken from the same areas during a second endoscopy in a later quiescent or exacerbated phase. During the active phase of pyloric stenosis, decreased levels of PGE_2 were found in the gastroduodenal tissues and secretions were compared with levels found during convalescence. These level differences were statistically significant. A correlation between the severity of the clinical and endoscopic findings and the PGE_2 levels was found. A further decrease in PGE_2 levels in the second endoscopy were indicative of the presence of scar tissue, representing an irreversible obstructive peptic disease.

(*Arch Surg* 1989;124:724-726)

Prostaglandin E_2 (PGE_2) and several other types of PGs have been shown to play a major role in the prevention of gastric mucosal lesions.[1] Initial studies suggested that the antiulcer effect of PGs was related to their known potent antisecretory properties. Subsequent experimental observations demonstrated that the mechanism of protection involved factors beyond simple inhibition of acid secretion. This ability of PGs to protect the cells has been termed *cytoprotection*.[2] The mechanism underlying gastric cytoprotection is not yet fully understood. Prostaglandins may enhance gastric musocal blood flow,[3] stimulate mucus and bicarbonate secretions,[4] improve synthesis of macromolecules and transport processes,[5] increase gastric mucosal cyclic adenosine monophosphate content,[6] and affect gastric motility.[7]

Clinical investigations revealed the possible beneficial effects of PG administration on the prevention and healing of gastric and duodenal lesions.[8] These observations raised the possibility that further decreases in PGE_2 levels may be present during duodenal ulcer complications and specifically during pyloric stenosis (PS). To evaluate this hypothesis, we studied the levels of PGE_2 in patients suffering from PS. A comparison was made between levels measured during active, quiescent, and exacerbated phases of the disease.

PATIENTS AND METHODS

Study Groups

Our study group consisted of 17 patients with duodenal ulcer. All presented at the emergency ward with symptoms of PS as the initial symptom of their peptic disease. Patients having had a history of duodenal ulcer were excluded from this study. None had received anti-PG or antiulcer drugs.

Pyloric stenosis was determined in all patients by the following criteria: (1) clinical—voluminous vomiting of gastric contents devoid of bile and a residual gastric aspirate volume above 700 mL/24 h, (2) laboratory—signs of dehydration with hemoconcentration accompanied by hypokalemic alkalosis, and (3) endoscopic findings—with a stenosed pyloric canal functional with a hyperemic, edematous, and friable mucosa or organic with a scarred rigid canal.

From admission to the emergency ward until gastroscopy was performed, nasogastric suction was continued, and no antiulcer medication was initiated. Gastroscopy was performed by the same endoscopist 12 to 24 hours from admission with a gastroscope. Premedication for gastroscopy consisted of fentanyl citrate,

Possible role of prostaglandin E_2 in pyloric stenosis pathogenesis.

0.05 mg, atropine sulfate, 0.5 mg, and diazepam, 5 mg, all administered intravenously.

At the initial gastroscopy before any endoscopic manipulation, gastric secretions were aspirated and sampled for PGE_2 determination, following which two biopsy specimens each were obtained from the gastric antrum (3 cm from the pylorus), gastric fundus, duodenal bulb, and ulcer margins. Each biopsy specimen weighing 1 mg was assayed for PGE_2 levels separately.

A third biopsy specimen from the ulcer margin was sent for pathologic examination to ascertain that no necrotic tissue was present, and a fourth biopsy specimen was obtained from the stenosed pyloric canal for histologic typing to substantiate the endoscopic impression of the kind of stenosis, either functional, with edematous mucosa, with chronic and acute inflammatory infiltrates, or organic, with fibrotic mucosal changes.

During the initial hospitalization, after gastroscopy was performed, all 17 patients received identical treatment with nasogastric suction, nutritional maintenance of 10 500 J (2500 calories) per day through total parenteral nutrition and 1600 mg of H_2 blocker (cimetidine) per day divided into four doses. On release from the hospital, the patients were given a rigid, appropriate, identical diet.

Of the 17 patients in our study group, 11 proved to have had a functional stenosis. Biopsy specimens from the pyloric canal showed the mucosa with chronic and acute inflammatory infiltrates. These patients responded to therapy well and became asymptomatic, whereby all symptoms of nausea and vomiting ceased, and were able to ingest normal quantities of food. They received H_2-blocker treatment for five weeks and underwent endoscopy again electively eight weeks from initial admission. During the three-week interval when no H_2-blocker drugs were ingested, no symptoms of PS had recurred, and before the repeated endoscopy, gastric rest was measured by nasogastric suction. In 11 patients (group A), gastric rest did not exceed 50 mL of bile-stained aspirate. Endoscopy was repeated at the same sites (twice each) as the initial endoscopy, and gastric aspirate was sampled for determination of PGE_2 levels. These levels were compared with those found at initial endoscopy.

The remaining six patients (group B) were found to have organic PS as proved histologically by fibrotic changes in the pyloric canal. With H_2-blocker treatment, they continued to suffer intermittent obstructive symptoms, with repeated nausea and vomiting of gastric contents after food ingestion. Four patients had to be rehospitalized when their symptoms intensified, whereupon a second endoscopy was performed (five to seven weeks after the first) after initial gastric aspirate volume was measured (average, 700 mL devoid of bile). The PGE_2 levels of the biopsy specimens and gastric aspirate were again assayed and compared with those determined on the first endoscopy. Two patients underwent endoscopy electively eight weeks after the first endoscopy for PGE_2 determination (H_2-blocker treatment was ceased three weeks before the second endoscopy) but were reported to be suffering from occasional vomiting and epigastric pain during the interim between endoscopies, with a slight intensification of the symptoms during the period without H_2-blocker treatment.

The presenting symptoms and endoscopic findings of both groups are given in Table 1. The statistical significance of PGE_2 difference was analyzed by Fisher's exact test.

PGE_2 Determination

The specimens were collected in plastic tubes and frozen immediately in liquid nitrogen and kept at −18°C until analysis. The quick freezing is necessary to avoid pertrubation of the tissue and the continual production of PGE_2 as a response to trauma. Biopsy material was homogenized in 1 mL of buffered acetate (40 nmol/L; pH, 4.0). Three volumes of ethyl acetate were added and mixed well, and the organic and aqueous phases were separated. This manipulation in an acidic pH environment helps eliminate arachidonic acid. The upper organic phase containing the PGE_2 was collected, and the ethyl acetate was evaporated. The yield of PG extraction as measured by labeled tritiated PGE_2 was over 90%. The residue was dissolved in buffered 0.1% sodium azide. The aqueous phase was used for protein determination. Prostaglandin E_2 was assayed using a PGE_2 radioimmunoassay kit.[9-13] The antibodies used in this kit showed 6% cross-reactivity with PGA_2, 3% with PGA_1, about 1% with 6-keto-PGE_1 and $PGE_{2\alpha}$, and less than 1% with all other PGs. The assay is reproducible within 5% in those done at different times. Protein was assayed by the Coomassie brilliant blue dye binding method with bovine serum albumin as standard.[14] The PGE_2 levels were expressed in picograms per milligrams of protein, with each patient serving as his own control.

As gastric secretions also contain protein, PGE_2 content was calculated in the sample material per protein content.

RESULTS

Of the 17 patients studied, 11 (group A) were found to present with pyloric spasm due to an active peptic disease. Their average age was 66.7 years. The presenting symptoms, consisting of vomiting, epigastric pain, and weight loss, together with endoscopic findings, are described in Table 1.

Prostaglandin E_2 levels from various sites sampled are given in Table 2. The increase in PGE_2 levels accompanying the clinical and endoscopic findings on repeated tests two months later are also shown in Table 2. This increase in PGE_2 levels was found to be of statistical significance ($P = .02$). The PGE_2 level increase was most marked in samples from the ulcer margins and gastric secretions.

Six patients (group B), with an average age of 69.3 years, had low PGE_2 levels found at first endoscopies on admission (Table 2). Repeated tests during their clinical deterioration showed both a deterioration in the endoscopic findings and a further decrease of statistical significance ($P < .05$) in PGE_2 levels (Table 2).

COMMENT

Pyloric stenosis is a complication of peptic ulcer disease. We believe that decreased levels of PGE_2 play an important role in the pathogenesis of this complication and aggravate the condition by a positive feedback mechanism (Figure). By causing functional gastric outlet obstruction and increased histamine release, active ulcer disease leads to increased gastric secretion, reduction of mucosal absorption, and gastric motility disturbance.[15-18] These are the pathophysiologic mechanisms that presumably play an important role in the pathogenesis of PS and that may be triggered or result from a PGE_2 level decrease.

This study confirms a decrease in PGE_2 levels during the active phase of pyloric spasm and stenosis and increased levels during convalescence. Conversely, a deterioration in the clinical and endoscopic findings was associated with a continued reduction in the PGE_2 level. A correlation was observed between the severity of the clinical and endoscopic findings and the decreased levels of PGE_2 in all sites tested. The six patients with true PS that did not heal and a demonstrated decrease in PGE_2 levels required bypass operations. We believe that the inability of the tissue to produce PGs indicates the presence of fibrosis rather than normal mucosa and represents an irreversible stage of the obstructed peptic disease. Group A showed both increased PGE_2 levels concomitant with clinical improvement and needed only conservative treatment. Our study does not answer the question of whether PGs are a cause or effect of PS, but a correlation between PG levels and PS severity was demonstrated.

We emphasize the relationship between complications of peptic disease and PGE_2 levels and suggest a possible pathophysiologic mechanism that could be applied in the treatment of PS due to an active peptic ulcer disease.

The Effect of Endotoxin on Glucose Metabolism in Skeletal Muscle Requires the Presence of Plasma

Joseph F. Amaral, MD; Jeffry D. Shearer, MA; Balduino Mastrofrancesco, MS; Donald S. Gann, MD; Michael D. Caldwell, MD, PhD

• The administration of endotoxin in vivo results in an increase in glucose utilization through an as yet undetermined mechanism. This study evaluated (1) the contribution of blood to the increased glucose utilization noted following endotoxemia, (2) the direct action of endotoxin on skeletal muscle glucose uptake in an isolated hindlimb perfusion system and in incubated muscle, and (3) the possibility that the increased glucose uptake in skeletal muscle mediated by endotoxin requires the presence of plasma. Incubation of blood with 50 and 100 mg/L of endotoxin increased glucose uptake and lactate production in a dose-dependent manner. Muscle incubations and perfusions in the absence of plasma and white blood cells showed that glucose uptake and lactate production were not affected by the presence of 50 to 250 mg/L of endotoxin, while 500 mg/L of endotoxin produced a 26.2% decrease in glucose uptake. In contrast, incubation of muscle in the presence of plasma and endotoxin increased glucose uptake by 37%. These findings suggest that (1) the increased glucose utilization of endotoxemia is only partially explained by increased glucose metabolism by blood, (2) endotoxin does not have a direct effect on the glucose uptake of skeletal muscle, and (3) an interaction of endotoxin with a component of plasma is required for an endotoxin-mediated increase in glucose utilization by skeletal muscle.

(*Arch Surg* 1989;124:727-732)

Endotoxemia and septic shock are characteristically associated with transient hyperglycemia, followed by sustained hypoglycemia.[1-5] The mechanism(s) for the hypoglycemia has been the object of considerable investigation, particularly in light of the finding that the prevention of hypoglycemia by the administration of intravenous glucose prevents death in animals subjected to endotoxemia.[6]

There are at least five possible mechanisms for the development of hypoglycemia after endotoxin administration as follows: (1) a decrease in glucose production, (2) an increase in glucose utilization, (3) a decrease in glucose intake, (4) an increase in the volume of distribution for glucose, and (5) an increase in the renal loss of glucose. The last three possibilities are unlikely to contribute substantially to the development of hypoglycemia by themselves, since a concomitant inhibition of glucose production would also be necessary. Furthermore, nephrectomized animals develop hypoglycemia in the presence of endotoxemia at the same rate as nonnephrectomized dogs,[7] the blood flow to the kidneys during endotoxemia is decreased rather than increased,[8] and urinary excretion of glucose is not detectable during endotoxemia.[9]

A considerable amount of evidence supports the possibility that endotoxin mediates a decrease in hepatic glucose production. Both in vitro[10,11] and in vivo[12-14] studies have shown a decrease in hepatic gluconeogenesis during endotoxemia. A possible mechanism for the depression in hepatic gluconeogenesis following the administration of endotoxin has been described by Moore and colleagues,[15] who noted an inhibition of hepatic phosphoenolpyruvate carboxykinase by a macrophage product. However, an impairment in hepatic gluconeogenesis does not appear to be sufficient to explain the hypoglycemia that develops during endotoxemia. For example, Kelleher et al[16] and Merrill and Spitzer[17] reported an increase in hepatic glucose production during septic shock in the presence of hypoglycemia; Peyton et al[14] described the more rapid development of hypoglycemia in eviscerated, endotoxin-treated dogs than in controls; and Wolfe et al[13] described the development of hypoglycemia in endotoxemia before the development of impaired gluconeogenesis. These data suggest that an increase in peripheral glucose utilization is also necessary for the development of hypoglycemia.

An increase in the peripheral utilization of glucose following the administration of endotoxin has been well documented by in vivo studies. Wolfe et al[13] and Kelleher et al[16] noted an increase in the disappearance of glucose during endotoxic and septic shock that was associated with an increase in lactate production. The heart, lungs,[18] and central nervous system[19] do not appear to contribute to the increase in glucose utilization. However, Hinshaw and colleagues[3,20] found an increase in glucose uptake by blood and by white blood cells in the presence of endotoxin, and Holley and Spitzer[21] and Witek-Janusek and Filkins[22] noted an increase in the oxidation of glucose by adipose tissue in the presence of endotoxin. Meszaros et al[23] recently described sustained increases in glucose utilization by organs rich in mononuclear phagocytes (the liver and spleen) and found no change in glucose uptake by the brain or testis in animals exposed to endotoxin.

Skeletal muscle, which constitutes 40% to 45% of the lean body mass and accounts for 30% of the total oxygen (O_2) consumption at rest,[24] is a probable site for the increased glucose utilization in response to endotoxin. In fact, recent studies that examined the metabolism of canine hindlimbs in vivo during endotoxemia have shown an increase in glucose uptake and lactate release.[4,5] These results were variably attributed either to a direct effect[5] or to an anoxic effect[4] of endotoxin on skeletal muscle. The latter explanation is unlikely, since an increase in glucose uptake and lactate production in the hindlimb tissue was noted even in the absence of anoxia.[5] Additional studies by Meszaros et al[25] showed that glucose uptake by skeletal muscle in vivo is increased transiently following administration of endotoxin. However, these in vivo studies did not address the mechanism for this endotoxin-mediated increase in glucose utilization by skeletal muscle.

The present study evaluated (1) the contribution of blood to the increased glucose utilization noted following endo-

toxemia, (2) the direct action of endotoxin on skeletal muscle glucose uptake in an isolated hindlimb perfusion system and in incubated muscle, and (3) the possibility that the increased glucose uptake in skeletal muscle mediated by endotoxin requires the presence of plasma.

MATERIALS AND METHODS

Animals and Anesthesia

Male Sprague-Dawley rats were used in all perfusions, and male Fisher rats were used in all incubations. These animals were housed under constant environmental conditions with 12-hour light-dark cycles and maintained on rat chow (RMH 3000, Agway Inc, Syracuse, NY) with free access to water. The mean ± SEM weight of rats used was 165 ± 2.5 g in the hindlimb perfusions, 60 ± 2.5 g in muscle incubations, 125 ± 2.5 g in epididymal fat pad incubations, and 350 ± 20 g in blood incubations. Rats were anesthetized before all experiments and procedures by the intraperitoneal injection (50 mg/kg of body weight) of a commercial preparation of pentobarbital sodium (Nembutal, Abbott Laboratories, North Chicago, Ill).

Epididymal Fat Pad Incubations

Epididymal fat pads were incubated by a modification of the technique of Witek-Janusek and Filkins.[22] A portion of an epididymal fat pad that weighed approximately 100 mg was isolated with a suture, removed, and rinsed with room temperature Krebs-Ringer bicarbonate buffer (KRBB). The fat pads were then preincubated at 37°C in glass vials that contained 2 mL of a continuously oxygenated (95% oxygen [O_2]: 5% carbon dioxide [CO_2]) incubation medium composed of KRBB, 4% bovine serum albumin, and 1 mmol/L of glucose. After a 30-minute preincubation, the fat pads were removed from the vials, washed in room temperature KRBB, and blotted. They were then placed in new glass vials that contained 2 mL of fresh, preoxygenated (O_2 pressure [Po_2] approximately equal to 600 mm Hg) incubation medium with uniformly labeled (U-[^{14}C]) glucose (0.1 μCi/mmol of glucose) and either no endotoxin, 250 mg/L of endotoxin, or 1794 pmol/L of insulin. The vials were then capped with rubber stoppers that held a center well (Kontes, Vineland, NJ) containing a filter paper wick and 200 μL of Scintisorb-C (Isolabs, Inc, Akron, Ohio) and incubated for one hour in a shaking water bath at 37°C. At the end of the incubation, the fat pads were removed, blotted dry, and weighed. A 500-μL aliquot of incubate was removed from the vial and stored at −80°C until assay. The vial was then recapped, and 1.5 mL of 0.7N perchloric acid was injected into the vial to evolve the dissolved CO_2 according to the method of Rodbell.[26] At the end of an additional hour of incubation, the center wells were removed and counted in 5 mL of Scintisorb-C.

Blood Incubations

Blood was removed from the abdominal aorta with heparinized syringes, pooled, and heparinized with 0.2 mL of heparin sodium (Elkins-Sinn, Inc, Cherry Hills, NJ) per 10 mL of blood. Blood was incubated in 2-mL aliquots for one hour in a shaking water bath at 37°C, with continuous oxygenation with 95% O_2:5% CO_2 without endotoxin or in the presence of 50 or 100 mg/L of endotoxin. At the end of the incubation, 1 mL of blood was removed for determination of the hematocrit; 1 mL of blood was centrifuged to obtain plasma, and the plasma was frozen until assayed for plasma glucose and lactate.

Perfusion Experiments

Overnight-fasted animals were placed in a Vanderbilt perfusion apparatus and surgically prepared for hindlimb perfusion using a previously described technique.[27] The perfusate consisted of continuously oxygenated KRBB containing 4% bovine serum albumin, 10 mmol/L of glucose with 0.05 μCi/mL of U-[^{14}C] glucose, 2 mmol/L of lactate, 0.2 mmol/L of pyruvate, physiologic amino acid concentrations,[27] and washed, outdated human erythrocytes that were added to give a hematocrit of 0.3.

Following a five-minute flow-through period and a 15-minute recirculating preperfusion at 10 mL/min, a 5-mL bolus of either KRBB alone, B5:55 *Escherichia coli* endotoxin (Sigma Chemical Co, St Louis) dissolved in KRBB, or insulin (Humalin, Eli Lilly & Co, Indianapolis) dissolved in KRBB was added to the perfusate.

Fig 1.—Glucose oxidation by fat pads. Incubation of fat pads with 250 mg/L of endotoxin (ETX) increased glucose oxidation by 32.1%. This response was less than that seen in presence of 1.8 nmol/L (250 mU/L) of insulin in which 525% increase in glucose oxidation was noted. There was no difference in initial specific activity of glucose in this experiment. Two asterisks indicate $P<.01$ vs control; dagger, $P<.01$ vs ETX.

Fig 2.—Glucose uptake and lactate production by blood. Glucose uptake and lactate production by blood were increased by 50 and 100 mg/L of endotoxin (ETX). Data are expressed on basis of whole blood. a indicates $P<.05$ vs control; b, $P<.01$ vs 50 mg/L of ETX.

The endotoxin was added to the perfusates to achieve an initial calculated concentration of endotoxin in the perfusate of 50 or 500 mg/L. Insulin was added to the perfusates to achieve an initial calculated concentration of insulin in the perfusate of 1.8 nmol/L (250 mU/L). The hindlimbs of animals in each group were then perfused at a constant flow rate of 10 mL/min in a recirculating mode for an additional 60 minutes. Arterial and venous perfusate samples were taken at 20-minute intervals. At the end of the perfusions, approximately 1 g of muscle was rapidly frozen using tongs as described by Wollenberger and colleagues[28] and stored at −80°C. The initial pH of the perfusate in all perfusions was 7.4 to

Fig 3.—Glucose metabolism in hindlimb perfusions. There was no alteration in glucose uptake, lactate production, or carbon dioxide (CO_2) production when hindlimbs were perfused with 50 mg/L of endotoxin (ETX) (panels at top). Perfusion of rat hindlimbs with 500 mg/L of endotoxin decreased glucose uptake by 26.2% with no alteration in lactate or CO_2 production (panels at center). In contrast, perfusion of hindlimb tissue with 1794 pmol/L of insulin increased glucose uptake by 90.2% and CO_2 production by 178.5% (panels at bottom). One asterisk indicates $P<.05$ vs control; two asterisks, $P<.01$ vs control; and BW, body weight.

7.5, and the initial arterial P_{O_2} was greater than 300 mm Hg. These values were relatively unchanged for the duration of each perfusion.

Muscle Incubation Technique

The extensor digitorum longus (EDL) muscles were incubated by a modification of the technique of Pain and Manchester.[29] The EDL muscles were rapidly removed, rinsed with room temperature KRBB, and placed on muscle holders to maintain resting length. The muscles were then preincubated at 37°C in polystyrene tubes that contained 3 mL of a continuously oxygenated (95% O_2:5% CO_2) incubation medium composed of KRBB (pH 7.4), 4% bovine serum albumin, and 1 or 5 mmol/L of glucose. After a 30-minute preincubation, the muscles were removed from the test tubes, washed in room temperature KRBB, and blotted. They were then placed in new incubation tubes that contained 3 mL of fresh incubate with U-[^{14}C] glucose (0.1 µCi/mmol of glucose) and either no endotoxin or 50 or 250 mg/L of endotoxin. The tubes were then incubated for one hour at 37°C in a shaking water bath with continuous oxygenation (95% O_2:5% CO_2). At the end of the one-hour incubation, the muscles were removed, washed in room temperature KRBB, blotted dry, rapidly frozen in liquid nitrogen, and stored at −80°C until assayed. The incubation medium was removed and stored at −80°C until assayed.

Fig 4.—Glucose uptake and lactate production in muscle incubation. There was no alteration in glucose uptake or lactate production when extensor digitorum longus (EDL) muscles were incubated with 50 mg/L of endotoxin (ETX) (panels at top) or 250 mg/L of ETX (panels at bottom) in standard incubate that did not contain white blood cells or plasma.

In a separate experiment, plasma obtained from centrifuged blood was incubated for one hour in the presence and absence of 50 mg/L of endotoxin. At the end of the incubation, U-[^{14}C] glucose was added to the plasma from both groups, and the plasma was divided into 3-mL aliquots. The EDL muscles were then incubated in the plasma for one hour using the method described above.

Analytical Methods

Perfusate samples were analyzed for CO_2 pressure, Po_2, and pH using a blood gas analyzer (IL Model 213 blood gas analyzer, Instrumentation Laboratories, Lexington, Mass). Perfusate glucose was determined by a glucose oxidase assay using a glucose analyzer (YSI-23A, Yellow Springs Instruments, Yellow Springs, Ohio). The glucose concentrations of the incubation media and the lactate concentrations of the incubation media and perfusate were determined by fluorometric assay[30] after deproteinization with 0.7N perchloric acid. Production of [^{14}C]O_2 was measured by injecting arterial and venous perfusate samples (1 mL) into the main compartment of counting vials. The counting vials contained center wells that held 0.2 mL of Scintisorb-C and filter paper wicks in gelatin capsules and 1 mL of 0.7N perchloric acid in the main compartment. After incubation of the counting vials in a shaking water bath at 37°C for one hour, the gelatin capsules in the center wells were removed and counted in 5 mL of Scintisorb-C. The specific activity of glucose and lactate in both incubate and perfusate was determined by a modification of the method of Rich et al.[31] Effluent peaks for glucose and lactate were separated by high-pressure liquid chromatography, collected, and then counted.

Calculations and Statistical Analysis of Results

The specific activity of U-[^{14}C] glucose remained constant throughout all experiments. As a result, the mean initial specific activity was used for all calculations in these experiments. In perfusion experiments, glucose uptake and lactate production were calculated on the basis of arterial concentrations at 20 and 80 minutes. All results were expressed on the basis of a 100-g body weight. In muscle incubation experiments, glucose disappearance from and lactate appearance into the incubation media were determined and expressed per total muscle. In epididymal fat pad incubations, results were expressed on a weight basis.

Statistical analyses were performed using a Student's t test or a one-way analysis of variance for overall differences with a Neuman-Keul test for intergroup differences.[32] All results are reported as mean ± SEM. Sample sizes for each experiment are noted in the figure legends.

RESULTS

Fat Pad Incubations

Fat pad incubations were performed to determine the biological activity of the endotoxin preparation used in these experiments. As shown in Fig 1, 250 mg/L of endotoxin increased glucose oxidation by 32.1% (15.6 ± 0.9 to 20.6 ± 1.8 cpm/h/mg of fat [$P<.01$]). This response was considerably less than that seen in the presence of 1.8 mmol/L of insulin in which a 525% increase in glucose oxidation was noted (15.6 ± 0.9 to 97.5 ± 10.1 cpm/h/mg of fat [$P<.001$]). There was no difference in the initial specific activity of glucose in these three experiments.

Blood Incubation

The mean initial blood glucose concentration was 6.0 ± 0.1 mmol/L of blood and that of lactate was 1.9 ± 0.02 mmol/L of blood. As shown in Fig 2, incubation of blood with 50 mg/L of endotoxin increased glucose uptake by blood by 30% ($P<.01$). Incubation of blood with 100 mg/L of endotoxin resulted in a further increase in glucose uptake. This was equivalent to a 41% increase vs control ($P<.01$) and a 9% increase vs blood incubated with 50 mg/L of endotoxin ($P<.01$).

Lactate production paralleled glucose uptake. As shown

in Fig 2, incubation of blood with 50 mg/L of endotoxin increased lactate production by blood by 10% ($P<.01$). Incubation of blood with 100 mg/L of endotoxin resulted in a further increase in lactate production. This was equivalent to a 24% increase vs control ($P<.01$) and a 12% increase vs blood incubated with 50 mg/L of endotoxin ($P<.01$).

Hindlimb Perfusion and Muscle Incubation Studies

There was no difference in glucose uptake, lactate production, or CO_2 production when hindlimbs were perfused with or without 50 mg/L of endotoxin (Fig 3). Similarly, the incubation of the EDL muscles with endotoxin in concentrations of 50 or 250 mg/L of medium did not alter glucose uptake or lactate production over controls (Fig 4).

The perfusion of rat hindlimbs with 500 μg of endotoxin per milliliter of perfusate decreased glucose uptake by 26.2% (1.22 ± 0.06 to 0.9 ± 0.12 μmol/min/100 g of body weight [$P<.05$]) (Fig 3). There was no alteration in lactate or CO_2 production in the presence of 500 mg/L of endotoxin (Fig 3). In contrast, perfusion of the hindlimb tissue with 1.8 nmol/L of insulin increased glucose uptake and CO_2 production by 90.2% and 178.5%, respectively, with no alteration in lactate production (Fig 3).

Muscle Incubations in Plasma

When the EDL muscles were incubated in plasma that contained 50 mg/L of endotoxin, glucose uptake was increased by 37.6% (1.89 ± 0.13 to 2.6 ± 0.07 μmol/min/EDL muscle [$P<.01$]), and lactate production was increased by 26.7% (0.45 ± 0.04 to 0.57 ± 0.01 μmol/min/EDL muscle [$P<.05$]) (Fig 5) over EDL muscles that were incubated in plasma without endotoxin. There was no decrease in the plasma concentration of glucose when plasma was incubated for one hour with and without 50 mg/L of endotoxin.

COMMENT

The increased utilization of glucose by peripheral tissue during endotoxemia has been well documented.[3-5,13,14,16] The results of the present experiments confirm the work of Hinshaw et al[3] in that there was an increase in glucose uptake and lactate production by blood in the presence of 50 mg/L of endotoxin. Furthermore, these studies demonstrate a dose response to endotoxin since glucose uptake and lactate production were greater at 100 mg/L of endotoxin than at 50 mg/L. This is in agreement with the work of Cohn and Morse,[33] who demonstrated a nonlinear dose response for glucose uptake by polymorphonuclear leukocytes as the concentration of endotoxin was increased above 10 mg/L.

To our knowledge, the contribution of an endotoxin-stimulated increase in glucose uptake and lactate production by blood cells to the overall increase in glucose uptake demonstrated by hindlimb tissue in in vivo studies has not been previously examined. Using the data obtained in the present studies for the rat, blood exposed to 50 mg/L of endotoxin would increase its glucose uptake by 0.017 μmol/min/mL. Assuming a blood volume in the rat of 7.5% of body weight, it can be calculated that blood could increase endotoxin-stimulated total-body glucose uptake by 7.4% (from 1.72 to 1.85 μmol/min/100 g of body weight). A similar calculation can be performed for the dog by using the data of Hinshaw et al[3] for the response of blood to endotoxin and the data of Romanosky et al[5] or Raymond et al[4] for the response of hind limb tissue in vivo to endotoxin. Assuming a blood volume of 8% body weight,[34]

Fig 5.—Glucose uptake and lactate production by skeletal muscle incubated in plasma ± endotoxin (ETX). Glucose uptake and lactate production by extensor digitorum longus (EDL) muscles were increased when incubated in plasma with 50 mg/L of ETX. One asterisk indicates $P<.05$ vs control.

the studies of Romanosky et al[5] would predict that the response of blood to the administration of endotoxin could result in an increase in glucose uptake of 13%, and the studies of Raymond et al[4] would predict an increase of 4.5% in the whole animal. Although a leukocytosis consequent to endotoxin exposure might further increase this difference, endotoxin-induced leukocytosis does not occur until four to six hours after exposure. Thus, the increase in the metabolism of glucose by blood in the presence of endotoxin is unlikely to account for the immediate difference in glucose uptake noted in in vivo studies following endotoxin administration. The studies of Meszaros et al[23,25] evaluated the contribution of other organs to the increased glucose consumption of endotoxemic rats. The largest increase in glucose uptake per unit weight was found in the liver and spleen. However, the major contributors to the increased glucose consumption were the skin, skeletal muscle, and intestine due to the large mass of these tissues.[23,25]

An increase in glucose uptake by skeletal muscle in the presence of endotoxin may result from a direct action of endotoxin on skeletal muscle. However, the present studies suggest that endotoxin does not have a direct effect on glucose uptake in the absence of white blood cells or hormones since perfusion and incubation of skeletal muscle with up to 250 mg/L of an endotoxin preparation (shown to alter glucose oxidation in adipose tissue and glucose uptake in blood) did not alter glucose uptake by the skeletal

muscle. The absence of an increase in glucose uptake cannot be attributed to an insensitivity of the preparation since, in concurrent experiments, perfusion with 1.8 nmol/L of insulin resulted in a 95% increase in glucose uptake. Furthermore, perfusion of skeletal muscle with a high concentration of endotoxin (500 mg/L) resulted in a 26.2% decrease in glucose uptake. This decrease could not be explained by interference of endotoxin with the glucose assay because addition of 500 mg/L of endotoxin to a glucose standard did not alter the measured glucose concentration of the standard. Thus, it does not appear that endotoxin directly mediates an increase in skeletal muscle glucose uptake.

However, skeletal muscle incubated in plasma with endotoxin demonstrated a 37% increase in glucose uptake. These findings suggest that an interaction of endotoxin with a plasma component is required to elicit an increase in glucose uptake by skeletal muscle by endotoxin. Which component of plasma is involved in this response remains to be investigated. Insulin or insulinlike factors are likely candidates for this interaction for the following reasons: (1) because these are the major known peripheral mediators of an increase in glucose uptake by skeletal muscle; (2) because diabetic rats are more resistant to the lethal action of endotoxin than nondiabetic rats[35]; and (3) because diabetic rats demonstrate prolonged hyperglycemia following endotoxin administration rather than hypoglycemia.[36] The third point occurs in the presence of unchanged glucose production and a decreased glucose clearance.[9] However, an increase in the plasma insulin concentration may not be necessary for an increase in glucose utilization during endotoxemia, since Romanosky et al[5] and Raymond et al[4] both noted increased glucose uptake in muscle in the absence of an increased plasma insulin concentration, and Adeleye et al[37] reported the development of hypoglycemia and elevated blood lactate concentrations in rats after the administration of endotoxin in the absence of hyperinsulinemia.

Several additional mechanisms by which endotoxin may mediate an increase in skeletal muscle glucose uptake are possible. Briefly, an increase in glucose uptake by skeletal muscle in the presence of endotoxin could also be the result of an alteration in substrate delivery to the muscle that is mediated by endotoxin. An increase in glucose uptake may result from tissue anoxia or ischemia. Finally, endotoxin may increase glucose uptake in skeletal muscle by stimulating the release of a product from white blood cells that, in turn, mediates the increase in glucose uptake.

In conclusion, endotoxin does not have a direct effect on the glucose uptake of skeletal muscle. An interaction of endotoxin with a component of plasma is required for an endotoxin-mediated increase in glucose utilization by skeletal muscle. The requirement of plasma for an endotoxin-mediated increase in glucose uptake by tissue other than skeletal muscle awaits further evaluation.

We thank Georgia Platonotis and William Henry for their excellent technical assistance.

Hypertonic Saline Resuscitation in a Porcine Model of Severe Hemorrhagic Shock

Gregory G. Stanford, MD; C. Richard Patterson, MD; Lynda Payne, RN; Timothy C. Fabian, MD

• The purpose of this study was to investigate the effect of 7.5% hypertonic saline solution (HTS) as the initial solution in resuscitation of a pig in shock. Twenty-two animals were bled 50% of their blood volume over 30 minutes and maintained in shock for 60 minutes. The 14 survivors were divided into two groups. The first group was given 20 mL/kg of lactated Ringer's solution (LR) over a ten-minute period, while the second group was given 10 mL/kg of HTS. Both groups were then given LR at 2 mL/kg/min until the mean arterial pressure reached 80 mm Hg. The HTS group achieved a more rapid rise in mean arterial pressure over the first ten minutes of resuscitation. During this period, the cardiac index increased significantly more in the HTS group when compared with the LR group. All animals in the HTS group developed an adequate urine output. Only two animals in the LR group developed an adequate urine output. Hypertonic saline solution markedly improved survival, and there were significant improvements in hemodynamics. This was accomplished with smaller volumes of resuscitation fluid and may prove useful under conditions where intravascular access is limited.

(*Arch Surg* 1989;124:733-736)

The rapid infusion of crystalloid solutions remains the cornerstone of early therapy for trauma victims in severe hemorrhagic shock. An alternative to conventional crystalloids for early fluid resuscitation is a crystalloid solution that may be effective in smaller volumes, permitting more rapid resuscitation. Hypertonic saline solution (HTS) and hyperosmotic solution used in small volumes have been beneficial in animal shock models[1-5] and human burns.[6-8] These studies have consistently shown marked hemodynamic improvement with the use of HTS to treat hemorrhagic shock; however, in most studies, these improvements have been transient. It appears that HTS is very effective in the treatment of hemorrhagic shock for a short period. On the other hand, in the early resuscitation of patients in hemorrhagic shock, when time is all important and the rate of infusion is limited, HTS may improve their circulatory status while more conventional methods of resuscitation are begun.

The purpose of this study was to compare a resuscitation regimen that incorporates an initial infusion of HTS in a porcine hemorrhagic shock model with one that incorporates lactated Ringer's solution (LR). We attempted to test the hypothesis that an initial infusion of HTS would restore hemodynamic stability more rapidly, since less volume would be required to do so.

MATERIALS AND METHODS

Twenty-two young female pigs (8 to 12 weeks old), weighing 15 to 20 kg, were obtained from a single supplier. All experiments were monitored and approved by the Animal Care Committee of the University of Tennessee, Memphis. On the morning of the experiment, each animal was sedated intramuscularly with ketamine hydrochloride (Ketaset, Bristol Laboratories, Syracuse, NY) in a dose of 10 mg/kg. An intravenous line was then established through which an additional 5 mg/kg of ketamine hydrochloride was injected. Many of the animals exhibited random, nonpurposeful muscular activity while under the influence of ketamine and were paralyzed with 1 mg of pancuronium bromide (Pavulon, Organon Laboratories, West Orange, NJ) to facilitate placement of the intravenous catheters. During this period, the pigs underwent mechanical ventilation with room air. After insertion of all necessary catheters, pancuronium was withheld, and the animals were spontaneously allowed to breathe room air. Mechanical ventilation was then only used in the occasional animal that became apneic during the hemorrhage phase of the experiment and was discontinued as soon as the animal resumed an adequate ventilatory pattern.

Catheters were placed in each external jugular vein for measurement of central venous pressure as well as administration of fluids during the resuscitation phase of the experiment. The femoral artery was used for continuous measurement of arterial pressure and collection of shed blood during the hemorrhage phase of the experiment. The femoral vein was used to pass a 7F Swan-Ganz catheter (American Edwards Laboratories, Irvine, Calif) into the pulmonary artery for measurement of pulmonary artery pressures, pulmonary capillary wedge pressure, and thermodilution cardiac outputs. When the catheter was not being used for cardiac output determinations, it was set to give continuous readings of central venous blood temperatures. The distal port was used for collection of mixed venous blood samples. A Foley catheter was inserted through a superpubic cystostomy to continuously monitor urine output.

After each animal had been prepared in this fashion, it was allowed to lie undisturbed for a 60-minute period to minimize the effect of the preparation on the subsequent experiment. Baseline measurements were taken at the end of this period. Over the next 30 minutes, each animal was bled 50% of its estimated blood volume based on the regression equation for swine reported by von Engelhardt[9]: estimated blood volume per kilogram = 95 (body weight)$^{-0.068}$. Over the subsequent 60 minutes, each animal was kept in shock by maintaining its mean arterial pressure (MAP) between 40 and 60 mm Hg by either reinfusing shed blood or withdrawing more blood. At the end of this shock period, the surviving animals were divided into two groups. One group, the HTS group, received 10 mL/kg of 7.5% hypertonic sodium chloride solution (2400 mOsm/L) over the first ten minutes of the experiment. The other group, the LR group, received 20 mL/kg of LR

during the same ten-minute period. For the remainder of the experiment, both groups received LR at the rate of 2 mL/kg/min until the end point of resuscitation was reached, at which time the rate of infusion was decreased to a maintenance rate of 2 mL/kg/h. The end point of resuscitation was defined as reaching and maintaining an MAP of 80 mm Hg for two consecutive measurements taken ten minutes apart.

Measurements of temperature, respirations, heart rate, arterial pressure, central venous pressure, pulmonary artery pressure, pulmonary capillary wedge pressure, cardiac output, and urine output were recorded at baseline, every ten minutes for the first 40 minutes of resuscitation, and every 20 minutes for the remainder of the experiment.

Blood samples for levels of sodium, lactate, potassium, bicarbonate, and arterial blood gas tensions were withdrawn from the femoral artery catheter and analyzed prior to hemorrhage (baseline), prior to resuscitation, and at the end of the experiment. Mixed venous blood gas tensions taken from the pulmonary artery catheter were analyzed at the same time points.

Statistical analyses were performed using the Wilcoxon paired *t* test. Body surface area was calculated using the formula of DuBois and DuBois[10]: body surface area $=$ height$^{0.725}$ $\times$ weight$^{0.425}$ $\times 0.007184$.

RESULTS

Of the 22 pigs entered into the study, eight animals did not survive the hemorrhage, yielding a mortality rate for this model of 36%. Fourteen animals survived the shock to enter the study: seven were placed in the LR group and seven in the HTS group. Of the seven animals placed in the LR group, two did not survive the two-hour resuscitation period. Five were successfully resuscitated, and two achieved an adequate urine output (defined as 2 mL/kg/h). Of the seven pigs placed in the HTS group, there were no deaths. All animals reached or exceeded an MAP of 80 mm Hg, and all regained an adequate urine output.

The animals in the LR group required an average of 2704 mL of intravenous fluid by the end of the resuscitation period, while those in the HTS group received an average of 1234 mL (46% of the LR group average). The animals in the LR group consistently required more volume of intravenous fluid to reach and maintain a stable blood pressure when compared with the HTS group so that, by the conclusion of the experiment, the animals in the LR group required an average of almost 2.5 times the volume received by the HTS group. Even though the HTS animals received markedly more sodium in the first ten minutes of resuscitation during the HTS infusion, as seen in Fig 1 (HTS group, 260 mmol/L; LR group, 60 mmol/L), both groups received similar amounts of sodium by the conclusion of the experiment (HTS group, 420 mmol/L; LR group, 360 mmol/L).

The MAP throughout the experiment is shown graphically in Fig 2. With the onset of resuscitation, there was an initial rapid increase in the HTS group following the 7.5% HTS infusion. At the conclusion of the HTS infusion, the MAP was significantly higher in the HTS group when compared with the LR group ($P<.05$). The MAP in the LR group rose more slowly, but after 30 minutes, both groups stabilized around 80 mm Hg for the remainder of the study period, with the LR group requiring more volume to maintain this pressure.

As shown in Fig 3, the cardiac index (CI) was seen to improve dramatically in both groups at the beginning of resuscitation but was significantly higher at ten minutes ($P<.05$) in the HTS group. The means for the two groups approached significance ($P<.07$) at 30 minutes, with the LR group being greater, but there were no other statistical differences between the two groups during the study period. Following this peak at the conclusion of the HTS infusion, the CI fell in the HTS group but remained above

Table 1.—Hematocrit and Serum Chemistry Changes

Variable	Group*	Baseline	End of Shock	End of Resuscitation
Hematocrit	LR	0.321 ± 0.053	0.211 ± 0.052	0.161 ± 0.036
	HTS	0.327 ± 0.033	0.257 ± 0.036	0.181 ± 0.023
Sodium, mmol/L	LR	141 ± 3.6	141 ± 7.0	138 ± 6.6
	HTS	140 ± 2.7	142 ± 4.5	158 ± 5.9
Potassium, mmol/L	LR	3.4 ± 0.6	4.0 ± 0.5	3.8 ± 0.6
	HTS	3.5 ± 0.6	4.0 ± 0.7	2.6 ± 0.9
Bicarbonate, mEq/L	LR	23.4 ± 1.8	11.6 ± 5.3	12.9 ± 7.0
	HTS	23.4 ± 3.1	9.4 ± 3.5	11.9 ± 2.4
Lactate, mmol/L	LR	3.9 ± 2.0	21.7 ± 16.3	14.9 ± 5.7
	HTS	5.7 ± 3.8	19.5 ± 4.2	15.9 ± 6.2

*LR indicates group given 20 mL/kg of lactated Ringer's solution; HTS, group given 10 mL/kg of 7.5% hypertonic saline solution.

Table 2.—Acid-Base and Oxygen Transport Changes*

Variable	Group	Baseline	End of Shock	End of Resuscitation
pH	LR	7.50 ± 0.10	7.30 ± 0.18	7.22 ± 0.14
	HTS	7.60 ± 0.09	7.25 ± 0.17	7.26 ± 0.13
Base deficit, mmol/L	LR	4.9 ± 3.2	21.0 ± 6.6	19.9 ± 8.1
	HTS	5.0 ± 2.3	25.5 ± 5.7	22.8 ± 2.2
Arterial O_2 content, mL/dL	LR	15.3 ± 1.8	9.6 ± 2.0	7.4 ± 1.7
	HTS	14.8 ± 2.9	11.3 ± 1.6	7.5 ± 1.2
$AVDo_2$, mL/dL	LR	5.8 ± 2.4	6.6 ± 2.4	3.2 ± 1.2
	HTS	4.6 ± 0.8	7.6 ± 1.3	3.4 ± 1.9
O_2 delivery mL/min/m²	LR	628 ± 71	165 ± 71	392 ± 137
	HTS	526 ± 99	214 ± 58	430 ± 89
O_2 consumption mL/min/m²	LR	235 ± 86	108 ± 48	157 ± 34

O_2 extraction ratio	LR	0.37 ± 0.11	0.69 ± 0.20	0.44 ± 0.22
	HTS	0.32 ± 0.04	0.68 ± 0.05	0.44 ± 0.22

*LR indicates group given 20 mL/kg of lactated Ringer's solution; HTS, group given 10 mL/kg of 7.5% hypertonic saline solution; and $AVDo_2$, arteriovenous oxygen difference.

baseline throughout the remainder of the experiment. The LR group CI peaked at 30 minutes and also remained above baseline for the remainder of the resuscitation period.

The systemic vascular resistance fell sharply in both groups during resuscitation when compared with the baseline. After reaching a minimum at ten minutes, the HTS group stabilized at a level somewhat higher than the LR group, but the differences between the groups were not significant. Values obtained for the hematocrit value and the sodium, potassium, bicarbonate, and lactate levels are shown in Table 1. The hematocrit value dropped to just over 50% of baseline in both groups. The sodium level was elevated to 158 mmol/L in the HTS group at the end of resuscitation but remained normal in the LR group. The potassium level did not change in either group. The bicarbonate level fell precipitously in both groups by the end of the shock period but had begun to recover by the end of resuscitation. The lactate level was predictably elevated by the hemorrhage but had begun to revert toward normal at the conclusion of the study in both groups.

Tissue oxygenation and acid-base data are illustrated in Table 2. The severe shock produced in this model is demonstrated by the presence of significant metabolic acidosis, elevated base deficit, and depression of both oxygen delivery and consumption, with a marked increase in the oxygen extraction ratio. At the end of resuscitation, both groups remained acidotic, but the base deficit was partially replenished. Oxygen delivery doubled from the shock level but did not reach the baseline values, which can be attributed to hemodilution and the fall in hematocrit value. The oxygen extraction ratio fell toward baseline, indicating at least a partial restoration of tissue perfusion.

COMMENT

The hemodynamic effects of HTS have been evaluated in several hemorrhagic shock models, with most studies involving canine models anesthetized with various regimens incorporating phenobarbital sodium. Few studies have reported hemorrhagic shock models involving ketamine anesthesia in the young pig. Ketamine has fewer hemodynamic side effects than barbiturates, even though it appears to stimulate the sympathoadrenal axis.[11,12] Pentobarbital sodium, on the other hand, disrupts the venous compensatory response to shock,[13,14] with a loss of venomotor tone.[15] In a study by Simon and Olsen,[16] pentobarbital alone produced greater abnormalities in relatively nutrient-rich capillary blood flow than did an acute 40% hemorrhage in the young pig. Ketamine was also chosen because it is often used clinically in hemorrhagic shock when the patient cannot tolerate more potent agents. Another benefit of this model is that the functional characteristics of the pig cardiovascular system more resemble those of humans[9,17]; studies in swine, therefore, may be more relevant to clinical applications.

The results presented herein demonstrate the rapid cardiovascular effects of HTS in hemorrhagic shock. Mean arterial pressure rose rapidly during and immediately following the infusion, and it was associated with the statistically significant early rise in the CI and the stroke index, when compared with isotonic crystalloid resuscitation, even though 60% less volume was required. The systemic vascular resistance fell below baseline values early in the resuscitation, which implied that the elevated arterial pressure and cardiac output resulted in a rapid increase in tissue blood flow and perfusion. Varying concentrations of HTS have been shown to increase the cardiac output when given to animals in both the shock and nonshock states. In normovolemic dogs, hyperosmolar solutions increased cardiac contractility[11,18] and gave ventricular work a lowered peripheral vascular resistance.[19] In mongrel dogs subjected to hemorrhage, 5.2% saline produced large initial increases in cardiac output, mesenteric flow, and oxygen consumption.[2] The cause of this inotropic effect, combined with arterial dilatation, was first thought to be a redistribution of fluid from the interstitium to the vascular system. Lopes et al[20] investigated the effect of HTS in the canine model, with and without vagotomy, and showed that vagally mediated reflex venoconstriction was triggered by the influx of HTS in the pulmonary vasculature. This mechanism may also contribute significantly to the effect of the solutions, as evidenced by the rapid improvement that follows initiation of treatment.

It is interesting to speculate that the improvements

described herein corresponded to the rapid infusion of sodium. As seen in Figs 1 and 3, the improvements seen in the first ten minutes of resuscitation were more closely related to the dose of sodium given than the volume. It is important to note that the animals in the LR group achieved hemodynamic stability only after they had received a similar amount of sodium as the HTS group at the time the latter became stable. The effect of HTS may be due to the sodium ion, but it could also be due to the chloride ion or the osmolar effect. Nonionic osmotic agents have been used in the treatment of hemorrhagic shock with similar results to those described herein[2,6,21]; however, the responses seen are more dramatic and prolonged if the resuscitative regimen incorporates sodium either as the bicarbonate or chloride salt. Sodium has profound effects at the cell membrane,[5] and it may help to restore the membrane potential damaged by the hypotensive insult and prevent the decompensation of the second phase of blood volume restitution, which is caused by the shift of fluid into the cell in severe hemorrhagic shock as described by Gann et al.[22] The increased interstitial sodium might also offset the plasma factor-mediated poisoning of the sodium pump described by Cunningham et al.[23] The extracellular fluid volume deficit described by Shires et al[24] may also be accompanied by a sodium deficit that is more rapidly corrected with HTS.

Another measure of the improved hemodynamic status in the animals receiving HTS was the rapid resumption of urine production. The rapid restoration of renal perfusion is not only indicative of increased cardiac output but may also be a secondary cause of decreased renal vascular resistance that is due to the increased osmolality and increased osmotic clearance as was shown by Gazitua et al.[25] In their study, the renal vascular resistance fell when HTS was infused into the renal artery. In a study by Yesberg et al,[26] intravenous HTS caused increases in urine flow, sodium and potassium excretion, vasopressin excretion, and free water reabsorption. Hypertonic solutions thus appear to aid renal preservation in hemorrhagic shock by triggering both the systemic effects of shortening the ischemic period and the direct effects on the renal parenchyma itself.

Although most investigators have described the effects of HTS as transient, Velasco et al[1] achieved improved survival and sustained recovery of blood pressure by restoring cardiac output and stroke volume to normal. In the present study, CI, stroke index, and left ventricular stroke work increased to levels higher than the prehemorrhage values, and then slowly declined to levels just above baseline. The animals receiving HTS had a marked hypernatremia following the conclusion of the experiment. There were no adverse effects that could be attributed to this finding. In studies done on human burns, patients reached serum sodium values as high as 170 mmol/L without any signs or symptoms of acute hypernatremia.[7,8] The serum sodium level rapidly fell after the conclusion of the infusion of HTS, as the added sodium was diluted in the extracellular water and excreted by the kidneys. These improvements continued throughout the two-hour resuscitation period; the animals required markedly less volume to maintain a stable cardiovascular status.

Although LR has been the fluid of choice for patients in shock, HTS may offer a superior alternative for the initial resuscitation of the patient in hemorrhagic shock. There are situations where LR cannot be infused as rapidly as necessary to reverse the hemodynamic derangements seen in the severely traumatized patient. A solution as effective as LR, but used in a much smaller volume, would aid in resuscitating these patients prior to their arrival at the hospital. The battlefield and other similar mass casualty situations would be other areas where HTS could be beneficial. As demonstrated in this study, HTS rapidly corrects many of the hemodynamic deficits caused by severe hemorrhage as effectively as larger volumes of LR. Hypertonic saline solution, when given either initially in the prehospital period or shortly after arrival, might improve a patient's survival by rapidly restoring tissue perfusion while conventional treatment modalities are begun.

Instructions for Authors

Manuscripts are to be sent by first-class mail to the Editor, Claude H. Organ, Jr, MD, Professor, Dept of Surgery, University of California–Davis, East Bay 1411 E 31st St, Oakland, CA 94602. The procedures listed must be followed carefully and all materials requested must be enclosed for prompt review and consideration for publication in the *Archives of Surgery*. Use the checklist to ensure completeness.

Manuscript Preparation.—*The original typescript and two high-quality copies* of the entire manuscript must be submitted, including copies of all illustrations, legends, tables, and references. All copy, including references, legends, and tables, must be typed double-spaced on 8½ × 11-in, heavy-duty white bond paper. Margins must be at least 1 in. If a word processor is used, do *not* use justified right margins.

Abstract.—*Submit an abstract* (135-word maximum) of the manuscript, which must include a statement of the problem, methods of study, results, and conclusions. The synopsis-abstract replaces a summary or conclusions.

Copyright.—*A copyright release* form signed by *all* authors of manuscripts, brief communications, and correspondence is required by the Copyright Revision Act of 1976. The following statement, dated and signed by all authors, may be used: **"In consideration of the American Medical Association's taking action in reviewing and editing my submission, the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the AMA in the event that such work is published by the AMA."**

Financial Interest.—List all affiliations with or financial involvement in any organization or entity with a direct financial interest in the subject matter or materials of the research discussed in the manuscript (eg, employment, consultancies, stock ownership). All such information will be held in confidence during the review process. Should the manuscript be accepted, the Editor will discuss with the author the extent of disclosure appropriate for publication.

References.—*References* should be listed in *consecutive numerical order* as they are cited in the text, *not alphabetically*. Once a reference is cited, all subsequent citations should be to the original number. All references must be cited in the text or tables. Unpublished data and personal communication may not be listed as references. References to journal articles should include (1) authors, (2) title, (3) journal name as abbreviated in *Index Medicus*, (4) year, (5) volume number, and (6) inclusive page numbers—in that order. References to books should include (1) authors, (2) chapter title, if any, (3) editor, if any, (4) title of book, (5) year, (6) city, and (7) publisher. Volume and edition numbers, specific pages, and name of translator should be included when appropriate. **The author is responsible for the accuracy and completeness of the references and for their correct text citation.**

Author Responsibility.—One author must be designated *corresponding author*, with his or her address and telephone number provided. All correspondence and copy editing are sent to this author. The corresponding author will receive an edited typescript rather than galley proofs for approval. The authors are responsible for all statements in their work, including changes made by the copy editor. Order reprints at the time the typescript is returned after editorial processing. Specify the address to which requests for reprints should be sent.

Titles.—*The title* must be *short*, specific, and clear. It cannot exceed 42 characters per line, including punctuation and spaces, and is limited to two lines. The title page should include the full names and academic affiliations of all authors. If the manuscript was presented at a meeting, indicate the name of the organization, the place, and the date on which it was read.

SI Units.—Use Système International (SI) measurements throughout the manuscript.

Illustrations.—Use only illustrations that clarify and augment the text. Submit illustrations in triplicate, unmounted and untrimmed. Do not send original artwork. Send high-contrast glossy prints (not photocopies). Figure number, name of senior author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. All lettering must be legible after reduction to column size. Artwork submitted for publication may be relettered to achieve uniformity of lettering style throughout the journal. Illustrations should preferably be in a proportion of 5 × 7 in. *Color illustrations* are accepted for publication if the editors believe that color will add significantly to the published manuscript. The ARCHIVES will pay only part of the expense of color reproduction and printing color illustrations. The author's share of the expense is $400 for up to six square finished illustratons that can be arranged on a one-page layout. Any additional illustrations or special effects will be billed to the author at cost. Positive color transparencies (35-mm preferred) must be submitted for an evaluation. Do not send color prints unless accompanied by original transparencies.

CHECKLIST FOR AUTHORS

Send:

- Three copies of manuscript.
- Three copies of synopsis-abstract.
- Three copies of attached photographs, legends, tables, and/or illustrations clearly marked as described in the instructions.
- A copyright release statement signed by *all* authors.
- The address and telephone number of the designated corresponding author.
- Send to Claude H. Organ, Jr, MD
  Archives of Surgery
  Professor, Dept. of Surgery
  University of California–Davis, East Bay
  1411 E 31st St
  Oakland, CA 94602
- Use sufficient postage.

(Continued on p 738.)

(Continued from p 737.)

Legends.—*Legends* must be typed double-spaced, beginning on a separate sheet of paper. Length is limited to a maximum of 40 words.

Tables.—Each table must be typed double-spaced, including all headings, on a separate sheet of 8½×11-in paper. Do not use larger-size paper. If a table must be continued, use a second sheet and repeat all heads and stubs. Each table must have a title.

Manuscript Acceptance.—Manuscripts are received with the understanding that they *are not* under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the ARCHIVES and may not be published elsewhere without permission from the publisher (AMA).

OTHER INFORMATION

Brief Clinical Notes.—The ARCHIVES welcomes the submission of Brief Clinical Notes for review. These are generally reports of cases that provide a new or unique contribution and are to consist of no more than 400 words, two references, and one illustration. The synopsis-abstract may not exceed 80 words.

Correspondence and Brief Communications.—The Editor is pleased to receive letters that pertain to material published in the ARCHIVES as well as brief communications concerning other matters of interest to our readers. An interesting case may be published as a brief communication. Such contributions should be 250 words or less, typewritten, double-spaced without an abstract, and clearly marked "for publication." No more than two references are permitted and illustrations or tables are acceptable only when essential to the message.

News and Announcements.—Brief notices may be submitted of meetings, seminars, or symposiums that are of interest to surgeons.

Acknowledgments.—Illustrations from other publications must be acknowledged. Include the following when applicable: authors, title of article, title of journal or book, volume number, pages, month and year. The publisher's permission to reprint must be submitted to the ARCHIVES when the manuscript has been formally accepted.

Statistical Review.—Manuscripts containing statistical evaluation should include the name and affiliation of the statistical reviewer.

Informed Consent.—Manuscripts reporting the results of experimental investigations on human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure(s) had been fully explained.

Reference to Patients.—Patients should be referred to by number or, in anecdotal reports, by fictitious given names. Real names or initials must not be used in the text, tables, or illustrations.

Photographic Consents.—A letter of consent must accompany all photographs of patients in which a possibility of identification exists. It is *not* sufficient to simply cover the eyes to mask identity.

AMA Manual of Style.—This 1988 edition, formerly the *Manual for Authors & Editors*, is available from Williams & Wilkins, 428 E Preston St, Baltimore, MD 21202. Single copy price: $24.95. A shipping charge is added on all orders not prepaid. If additional ordering information is needed, or to order by telephone, call 1-800-638-0672.

PARTNERS PRACTICING GOOD MEDICINE.

Bring your outstanding surgical skills to the Southern California Permanente Medical Group and experience the freedom to focus on patient work. Not paperwork.

We are a well-established, prepaid health care program. Our multispecialty group practice is composed of and managed by SCPMG physicians.

Opportunities exist for board eligible/certified **Surgeons** with a combined practice of Peripheral Vascular and General Surgery.

Consider the advantages: the finest equipment and latest technology; the availability of consultations with other physicians of distinction; and a broad network of exceptional support personnel backed by the resources of one of the nation's leading HMO's.

Our compensation is competitive and benefits are outstanding. They include: professional liability, medical and dental coverage, vacation and sick leave, continuing education, life insurance and retirement plans. **After two years full-time employment, physicians are eligible to be considered for partnership.**

For a physician application, please call (800) 328-5278. If calling from outside of California, please call (800) 541-7946 or send your curriculum vitae to: Physician Recruitment, Dept. 018, Walnut Center, Pasadena, CA 91188-8013.

Percutaneous Nephrostomy in the Management of Renal Candidiasis

Orlando Ortiz, MD, Won J. Lee, MD

• **A case of *Candida* infection of the kidney was successfully managed by percutaneous means. This case demonstrates that percutaneous nephrostomy is a simple, effective technique not only for drainage, extraction of fungus balls, and irrigation with amphotericin B, but also for examining the renal collecting system and obtaining urine samples for diagnostic culture verification. Because of the toxicity of antifungal drugs, the incorporation of this percutaneous technique into standard management will benefit the patient with a life-threatening renal fungal infection.**

(*Arch Surg* 1989;124:739-740)

Fungal infections of the urinary tract are uncommon but seem to be increasing in frequency partly due to an increase in opportunistic infection from the common complication of modern therapeutics and debilitating disease.[1,2] As one indicator, the medical literature has seen an almost 400% increase in the reporting of genitourinary fungal infections.[3] Such infections are predominantly candidal and have become increasingly prevalent because of the alteration of host resistance caused by aggressive use of broad-spectrum antibiotics, corticosteroids, and immunosuppressive agents. Most fungal infections of the upper urinary tract involve the drainage structures rather than the renal parenchyma and produce fungal pyonephrosis.[4] We report a case of renal candidiasis in an adult in which percutaneous nephrostomy was used to counteract this pathophysiologic condition via extraction of the fungus ball, drainage, and antifungal irrigation of the renal collecting system.

REPORT OF A CASE

A 59-year-old man with a history of diet-controlled diabetes mellitus, hypertension, chronic renal failure, and multiple urinary tract infections complained of left flank pain and fever. His medical history included left-sided nephrolithiasis that had required pyelolithotomy six years prior to the current admission. Four years after this initial episode, the patient underwent ureteral surgery for left ureteral stricture. The patient subsequently underwent multiple urologic procedures for left-sided obstructive uropathy complicated by *Candida* sepsis. In addition, a nonfunctioning right kidney had been identified two years prior to admission. Physical examination at the time of admission revealed left costovertebral angle tenderness.

Significant laboratory findings were a serum urea nitrogen level of 50 mmol/L of urea, a serum creatinine level of 1360 μmol/L, and a white blood cell count of 20.2×10^9/L. Urine Gram's stain did not demonstrate any yeast forms but did show gram-positive cocci that were later identified as enterococci. A left percutaneous nephrostomy was performed on the third hospital day; nephrostogram showed marked hydronephrosis, with small, irregular filling defects in the renal collecting system representing fungus ball and debris, which were evacuated via nephrostomy tube (Figure). Blood and urine cultures revealed *C albicans*. Systemic and local amphotericin B were added to the antibiotics being given. Noncontrast computed tomography immediately after percutaneous nephrostomy revealed a nephrostomy-induced perinephric hematoma, which required no additional management.

His condition improved, and prior to discharge an arteriovenous fistula was placed for long-term hemodialysis. His serum urea nitrogen and serum creatinine levels steadily improved for three months while the percutaneous nephrostomy tube was in place. Other than a clogged arteriovenous graft, which required emergency thrombectomy, the patient remained asymptomatic for 12 months following the nephrostomy tube removal.

COMMENT

Renal candidiasis with fungus ball formation remains an uncommon entity, though its frequency has increased over the past few decades. Nonetheless, the significant morbidity and potential mortality associated with this condition make it imperative that a diagnosis be arrived at as expeditiously as possible. The afflicted patient already may have impaired health status. In addition, since the involved therapies are not without inherent risks, it is extremely important that the correct diagnosis be made.

Renal candidiasis is an uncommon presentation of an organism that, under normal circumstances, is commonly found within the human host. When host resistance is altered, the organism may assume pathogenic properties. Possible predisposing factors include the following: (1) states of compromised health (diabetes mellitus, acquired immunodeficiency syndrome, premature birth, or chronic debilitating illness); (2) pregnancy; (3) disturbance of urine flow (congenital genitourinary anomalies, neurogenic bladder, ureteropelvic junction obstruction, nephrolithiasis, genitourinary tuberculosis, ileal conduit, or other genitourinary surgery); (4) drugs (antibiotics, steroids, chemotherapy, or drug abuse); (5) radiation therapy; (6) major surgery or renal transplant; (7) trauma; and (8) indwelling catheter devices.[5] Under these circumstances, the patient may remain asymptomatic or may develop fever, flank pain, hematuria, dysuria, anuria, or renal failure.[6] The clinical presentation, therefore, will identify pertinent risk factors and symptoms that may herald a renal fungal process.

Laboratory findings demonstrate that less than 5% of clean-voided urine specimens should be expected to yield yeast in culture and that candiduria, in many instances, reflects improper collection, sampling, and processing of urine specimens.[7] Nevertheless, the presence of yeast in the urine warrants serious attention in the compromised host. It has been reported that a candidal colony count of 10 000 to 15 000 per milliliter in the absence of an indwelling Foley catheter represents a useful index of separation between colonization and infection.[8] It is also important to stress that though *Candida* is the most common cause of fungus balls in the genitourinary tract, *Penicillium*, Phycomycetes, and *Aspergillus* fungus balls can also occur. Renal fungus balls can also result from systemic fungal disease, as the kidney is involved in over 85% of cases of systemic candidiasis.[9]

Despite a wide selection of imaging modalities, a definitive diagnosis of fungus ball often remains elusive. This phenomenon can partly be explained by the composition

Accepted for publication March 10, 1988.

Reprint requests to Long Island Jewish Medical Center, New Hyde Park, NY 11042 (Dr Lee).

Nephrostogram showing hydronephrosis and irregular filling defects simulating blood clots, stones, or debris. Double pigtail ureteral stent is noted in place.

and location of the fungus ball. The fungus ball represents a conglomerate of hyphal elements and exudative debris resulting from inflamed, necrotic tissue within the renal collecting system.

The findings on plain-film roentgenography are highly nonspecific. Excretory urography may yield a smooth, mobile filling defect within the renal pelvis or an elongated, castlike ureteral filling defect.[2] Other, less specific features include a nonvisualized kidney, a delayed nephrogram, calyceal blunting or widening, hydronephrosis, hydroureter, or nodular ureteral filling defects. The diagnosis is confounded by the fact that many of these abnormalities are associated with tumor, calculus, blood clot, or papillary necrosis.

Noncontrast computed tomography will identify a nonradiopaque calculus due to the increased density resulting from the crystal structure of the calculus, and then one must differentiate between blood clot, sloughed papilla, tumor, and fungus ball.[6] Ultrasonometry readily detects hydronephrosis and can potentially detect an echogenic, nonshadowing mass in the renal pelvis.[10] As with excretory urography, retrograde pyelography may reveal a filling defect in the renal collecting system. From a nonimaging standpoint, ureterorenoscopy may also assist in evaluating the renal collecting system, as well as in extracting a fungal mass. Obviously, though beneficial, these tests do not always provide the clinician with the exact diagnosis.

Percutaneous nephrostomy is a versatile approach combining diagnostic and therapeutic modalities. Indications for percutaneous nephrostomy are relief of obstruction, confirmation of the diagnosis, and aggressive administration of fungicides. Percutaneous nephrostomy is performed under local anesthesia with an aseptic technique. In skilled hands, this procedure exposes the patient to minimal morbidity.[1] Not only can antegrade pyelography be performed, but aspirates from the renal pelvis can also be studied to determine the presence of fungi. The presence of a mobile filling defect in the collecting system with a positive aspirate virtually confirms the diagnosis of a fungus ball. An attempt is made to extract and thereby debulk the fungal mass. The usefulness of this maneuver is twofold: it reduces the possibility of distal ureteral obstruction by fungal debris and shortens the interval of irrigation required for sterilization of the renal pelvis.[11]

Local irrigation with an antifungal agent is performed via the nephrostomy tube. We consider 50 mg of amphotericin B prepared in 1 L of water to be a safe nephrostomy tube dose, and administration can be discontinued after five days if the blood cultures are sterile. The therapeutic goal is to relieve obstructive uropathy and completely eradicate all fungal organisms from the renal collecting system. Concurrent systemic antifungal therapy may also be administered. The most effective and only parenteral agent, amphotericin B, has serious side effects, such as hepatic dysfunction, nephrotoxic changes, gastrointestinal disturbances, hypotension, electrolyte derangements, and anaphylactoid reactions.

Large perirenal hematoma was demonstrated on computed tomographic scan. In one of the first reviews of the percutaneous nephrostomy, which encompassed 1207 patients, Stables[12] found significant bleeding in 1.3%. We found perirenal hematomas not requiring treatment in three of the 20 patients we studied by computed tomography following percutaneous nephrolithotomy.[13] To minimize the frequency of blood loss after percutaneous nephrostomy, any clotting abnormalities should be corrected before the procedure, and the operator should choose the puncture site carefully through Brodel's avascular line.

Percutaneous nephrostomy has proved to be extremely useful in the management of fungus ball and renal drainage. It supplements the previously described diagnostic modalities and affords a relatively less invasive means of treatment, thus obviating the need for surgery in these characteristically high-risk patients.

Peter G. Herman, MD, reviewed the manuscript and provided editorial guidance. Patricia Petersen assisted in preparing the manuscript.

Echinococcal Disease in an Extended Family and Review of the Literature

CPT Franco Musio, MC, USA, Dimitrios Linos, MD

• Echinococcal disease occurred in an extended family from Athens, Greece. Seven of the 11 family members were noted to be infected with *Echinococcus granulosus*, and five members have undergone surgical treatment. The potential sources of infection are discussed, although localization was impossible. There is no genetic basis for this disease and no apparent pattern of family member interrelationship or visceral involvement. Although echinococcal infection is frequently diagnosed in large urban centers, its transmission within a family is rare. Review of the literature and the current diagnostic and therapeutic measures are presented.
(*Arch Surg* 1989;124:741-744)

Echinococcal disease has plagued mankind from the time of Hippocrates, who most likely was referring to this condition in his description of patients with "livers full of water." The words *Echinococcus* and *hydatid* are derived from the ancient Greek language meaning "hedgehog berry" and "a drop of water," respectively. Infection by the parasite most commonly involves the liver, followed by the lungs, with the spleen,[1] central nervous system,[2] muscles,[3] kidneys,[4] adrenal glands,[5] heart,[6] bones,[7] retroperitoneum,[8] and other organs being affected with much less frequency. According to Fossati,[9] the "familial" form of echinococcosis was first mentioned by Thorstensen in 1840 and later described by Krabbe in 1866 as a "chronic disease which in the opinion of those in Ireland is hereditary." Deve,[10] in 1907, was the first to conduct an in-depth study of a number of family members afflicted with the echinococcal cysts in regard to the clinical features and pulmonary and hepatic locations. In 1946, Ferro[11] examined 29 affected families with a total of 66 cases, 59% of which were found between siblings. Since then, there have been scattered reports in the literature of the parasite affecting nuclear and extended families. There is no genetic basis for the disease, because human echinococcal infection is transmitted from the definite host to humans via the fecal-oral route.

Although relatively rare in the United States, echinococcal disease may still be diagnosed in large urban centers and also transmitted within a family. Such a case of echinococcosis occurred in seven of 11 members of an extended family from Athens, Greece, who were infected with *Echinococcus granulosus*, five of whom have undergone surgical treatment (Fig 1). These patients are described, with a review of the current diagnostic and therapeutic methods applied in the management of this disease.

REPORT OF CASES

Case 1.—A 52-year-old woman had previously been in good health. The patient discovered a mass directly beneath the right costal margin in May 1985. Abdominal roentgenograms were normal. In September 1985, the patient presented with dyspnea and shortness of breath. Chest roentgenograms demonstrated multiple lesions on both lungs (Fig 2), and an abdominal ultrasound study revealed multiple echogenic lucencies in both hepatic lobes. Chest and abdominal computed tomographic scans demonstrated multiple, round, low-density lesions in both lung fields (Fig 3) and in both hepatic lobes, respectively. Although the initial clinical impression was that of malignancy, subsequent measurement of serum antiechinococcal antibodies by radioimmunoassay was positive.

Fig 1.—Pedigree of case reports.

A laporotomy was performed in late September 1985, in which multiple hepatic cysts were found. Evacuation and sterilization of each cyst was done using hypertonic saline solution. Deep O-chromic sutures on a liver needle were used to approximate the uncalcified walls of each cavity. Two drains were left in the subhepatic space. Histologic analysis was consistent with a diagnosis of *E granulosus*. The postoperative course was uneventful, and no further symptoms were noted until February 1986, when the patient presented with dyspnea and shortness of breath. Chest roentgenograms demonstrated transformation of a previously seen left inferior, round, radiodense pulmonary lesion to a well-circumscribed air-fluid level. Intravenous antibiosis was commenced, with rapid improvement of symptoms.

The patient most recently presented in April 1987 with fever, anorexia, and right-sided chest pains. Chest roentgenograms demonstrated a similar progression of a previously seen right inferior, round, radiodense pulmonary lesion to a well-circumscribed air-fluid level. In May 1987, a right thoracotomy was performed, with removal of all cysts. The patient's symptoms have subsided during the postoperative course, and she is awaiting surgical treatment of the left pulmonary lesions.

Case 2.—A 70-year-old man, the husband of patient 1, had previously been in good health. Routine chest roentgenograms obtained two years before his presentation showed no abnormalities, although radioimmunoassay studies of serum samples were positive for antiechinococcal antibodies. A subsequent abdominal computed tomographic scan demonstrated a right hepatic cyst measuring 10 cm in diameter as well as a right renal cyst. The patient refused to undergo surgery.

Case 3.—A 25-year-old woman, the daughter of patients 1 and 2, had previously been in good health and had been married for the last two years. A routine chest roentgenogram obtained on January 1986 demonstrated a left inferior pulmonary lesion. Chest and abdominal computed tomographic scans were abnormal for one pulmonary and multiple hepatic cysts, respectively (Fig 4). The patient underwent a left thoracotomy in October 1986, with the removal of the pulmonary cyst, and laparotomy in March 1986, with evacuation of all hepatic cysts and obliteration of the cavities by approximating their uncalcified walls. Histologic analysis of all

Fig 2. — Posteroanterior (left) and lateral (right) chest roentgenograms demonstrating multiple pulmonary lesions (case 1).

Fig 3. — Chest computed tomographic scan demonstrating multiple pulmonary lesions (case 1).

Fig 4.—Abdominal computed tomographic scan demonstrating multiple hepatic lesions (case 3).

cysts was consistent with a diagnosis of *E granulosus*. The postoperative course has been normal.

Case 4.—A 64-year-old woman, the mother-in-law of patient 3, was previously in good health until January 1986, when she presented with right upper quadrant pains. Workup revealed cholelithiasis, and an abdominal computed tomographic scan showed four hepatic cysts. The serum sample was positive by radioimmunoassay for antiecchinococcal antibodies. The patient underwent cholecystectomy in January 1986, with synchronous treatment of the hepatic cysts. In this case, the large cavity was closed by omentoplasty, and the remaining ones were obliterated by approximation of their uncalcified walls. Histologic analysis was consistent with a diagnosis of *E granulosus*. The postoperative course was normal.

Case 5.—A 29-year-old woman, the daughter-in-law of patient 4, had previously been in good health. Routine chest roentgenograms in March 1986 demonstrated a right inferior, round, radiodense pulmonary lesion. A thoracotomy revealed a cyst, which was removed and proved to be *E granulosus* by histologic study. The postoperative course was normal.

Case 6.—A 64-year-old man, the father of patient 5, had undergone two separate thoracotomies, with the removal of pulmonary echinococcal cysts, and two laparotomies, with evacuation of hepatic echinococcal cysts. All procedures were performed at another institution.

Case 7.—A 58-year-old woman, the mother of patient 5, had chest roentgenograms and abdominal computed tomographic scans that were normal. Serum antiechinococcal antibody tests by radioimmunoassay were positive. She is being followed up.

The remaining members of the extended family have been tested serologically and are negative for antiechinococcal antibodies.

COMMENT

Echinococcosis in humans results from infection by *E granulosus* or *Echinococcus alveolaris* (multilocularis). The latter infection is rare and only forms 2% to 3% of all known cases of the disease.[12] The involvement of humans in the life cycle commences with ingestion of the ova, which is released in the stool of the definite host. The infection is usually due to eating unboiled vegetables contaminated by the feces of dogs as well as cats, wolves, and foxes. The eggs may also be carried directly from the dog or cat to the mouth of the child or adult. Contamination of well water by such infected carnivores may also serve as a potential source of infection. Once the egg is swallowed, it develops into the six-hooklet embryo that penetrates the intestinal mucosa and is carried to the liver by the portal vein, where the primary filtering and trapping occurs. Occasionally, the embryo can escape from the liver and travel to the lungs, with rare progression beyond this second filter to the central circulation and other organs.[1-8] Rarely, the embryo may enter the lymphatic circulation from the intestinal mucosa and be carried directly to the lungs via the thoracic and mediastinal lymph vessels. The embryo grows into a cyst consisting of an external cuticle

and an inner germinal epithelium. *Echinococcus granulosus* develops into a unilocular cyst that grows slowly over many years and does not penetrate tissue. The hydatid cyst of *E alveolaris* is always multilocular, with active invasion of the host tissue by germinal layer extensions. The life cycle of the parasite is complete as dogs and other carnivores eat the flesh or liver of previously infected intermediate hosts such as sheep, cattle, and pigs. This is a logical explanation for the prevalence of the disease in locations such as Greece, Australia, Central Europe, the Middle East, South America, southwestern Canada, and Alaska, where sheep and cattle breeding are important activities and there is close contact between animals and humans. The cyst develops into the adult worm in the jejunum of the definite host that measures 4 to 6 mm and resides for up to 20 months before releasing its eggs.

There seems to be no definitive pattern of family member interrelationship or visceral involvement in this "familial" form of echinococcal disease. The world literature in the last 20 years contains several accounts of identical organ infection within families to include only lung,[13] liver,[14] or muscle.[3] Fossati[9] described 24 sheep-herding families, 11 of which harbored solely pulmonary infection and five of which had solely hepatic infection among the members. Also, families such as the one we described are reported to have combinations of lung, liver, and other organ involvement.[15-18] Both types of *Echinococcus* were found in one couple from the French Jura, the wife diagnosed as having a large splenic *E granulosus* cyst and the husband having hepatic cysts of *E alveolaris*.[19] In offering a cause, a family dog was reported in only three cases,[3,15,17] and close animal association was noted in one study involving a community with constant contact between family members and dogs and sheep.[9] In our study, a pet dog was kept by the principal family of patients 1 through 3, although the other infected individuals had no contact with this animal. This dog was examined by a local veterinarian and found not to carry the parasite. All the family members lived in middle-class neighborhoods of Athens proper and had no association with apparent sources of infection, such as animals, farms, well water, other individuals harboring the organism. All the women of the family were housewives. All the men of the family, with the exception of the brother and husband of patient 3, were co-owners and clerks in a small retail store of wool products. The brother of patient 3 was a high school student. The husband of patient 3 was a butcher. Although no signs or symptoms of infection were noted in this individual, his mother, sister-in-law, and her parents had visceral involvement, antiechinococcal antibodies, or both demonstrated by radioimmunoassay. Notwithstanding the exposure of the butcher to animal viscera (in particular, lamb), his consideration as a source of infection is unlikely.

The affliction of an extended family with this disease is rare. Nevertheless, it is necessary to examine all members of the family of the afflicted patient. Computed tomographic and ultrasound scans as well as the modern serologic tests (indirect hemagglutination, complement fixation, enzyme-linked immunosorbent assay, and specific hydatid IgE tests)[20] are highly sensitive and specific and have facilitated the diagnosis of echinococcal disease. The surgical treatment of the liver echinococcosis consists of removal of the hydatid cyst, with careful protection of the abdomen from spillage of the hydatid fluid and obliteration of the remaining cavity using the many different described techniques—primary suturing,[21] omentoplasty,[22] capitonage,[23] and capsulorraphy. Before removal of the cyst, evacuation of the hydatic fluid followed by injection of hypertonic saline or silver nitrate solution is indicated to sterilize the contents. The surgical treatment of an uncomplicated hydatid cyst of the lung is much easier in that a simple incision of the surrounding pleura in conjunction with increased intrapulmonary pressure provided by the anesthesiologist will "pop out" the intact cyst. A simple suturing of the site of the delivered cyst suffices.

Medical treatment of hydatid disease has centered on the broad-spectrum antihelminthic agent mebendazole. After its initial introduction by Bekhti et al[24] in 1977, clinical studies have demonstrated the ability of mebendazole to sterilize hydatid cyst cavities.[25,26] A recently completed ten-year clinical trial of continuous therapy demonstrated increased life expectancy, subjective improvement, substantial radiologic decrease in the size of hepatic lesions, and lack of progression of distant metastases.[27] Mebendazole has therefore been recommended by many groups as a preoperative agent in inactivating the cyst and preventing possible scoliceal dissemination during surgery or for use in inoperable conditions.

Brief Clinical Note

Emergent Endoscopic Retrograde Cholangiopancreatography

A Highly Specific Test for Acute Pancreatic Trauma

Sharon R. Hayward, MD; Charles E. Lucas, MD; Choichi Sugawa, MD; Anna M. Ledgerwood, MD

• Emergent endoscopic retrograde cholangiopancreatography (ERCP) was assessed as the definitive diagnostic test for acute pancreatic injury in a 23-year-old male automobile driver who sustained blunt abdominal trauma. Despite the patient's quiet, tender abdomen, rising serum amylase level, and an abdominal computed tomographic scan demonstrating probable pancreatic transection, a nonoperative approach was successful when an emergency ERCP demonstrated normal ductal anatomy. This approach is advocated when the presence of a possible pancreatic injury is the only reason for a planned exploratory laparotomy.

(*Arch Surg* 1989;124:745-746)

Endoscopic retrograde cholangiopancreatography (ERCP), a valuable diagnostic test for pancreatic disease, is now being advocated for acute pancreatic trauma.[1] This report highlights a situation where early ERCP permitted successful nonoperative therapy despite abdominal tenderness and computed tomographic (CT) findings indicating transection of the distal pancreas.

REPORT OF A CASE

A 23-year-old man driving his car had a collision with a truck, during which the lower portion of his chest and upper portion of his abdomen bent the steering wheel. He was momentarily unconscious, and findings when he arrived for treatment elsewhere included stable vital signs, multiple facial abrasions, a closed right femur fracture, hypoactive bowel sounds, and diffuse abdominal tenderness greatest in the epigastrium and left upper quadrant (LUQ). Amylase levels at admission were 50 U/L and rose to 240 U/L in two hours. His hemoglobin level was 150 g/L. Chest, abdomen, cervical spine, skull, and pelvis roentgenograms were normal. A peritoneal lavage yielded normal findings (red blood cell count, 4.0×10^{12}/L; no bilirubin; no amylase). A CT scan revealed a probable transverse fracture of the distal pancreas (Fig 1). On transfer to Detroit Receiving Hospital for abdominal exploration, vital signs and hemoglobin level remained stable. Epigastric and LUQ tenderness persisted. His amylase level had risen to 478 U/L. Twelve hours after injury and two hours after arrival to Detroit Receiving Hospital, an emergency ERCP demonstrated a completely normal pancreatic duct without any extravasation (Fig 2). The patient was then treated nonoperatively with nasogastric suction until pain ceased on day 8 when a

Fig 1.—Abdominal computed tomographic scan demonstrating probable transverse fracture of distal pancreas (arrow).

Fig 2.—Endoscopic retrograde pancreatography with pancreatogram demonstrating an intact ductal system without extravasation of dye.

progressive diet was started. Amylase level peaked on day 2 at 490 U/L and then decreased to 160 U/L by day 6. After operative fixation of the femur fracture on day 8, he was discharged home on day 14. Follow-up abdominal CT scan and serum amylase level at six weeks were normal.

COMMENT

Blunt pancreatic trauma must be suspected after all severe injuries. When associated intraperitoneal injuries are absent, the decision to explore for suspected pancreatic injury is based on abdominal tenderness and a rising serum amylase level as the earliest clues.[2] Both were present in this patient who, in the past, would have undergone laparotomy. Emergency ERCP in the face of abdominal tenderness, a quiet abdomen, a rising serum amylase level, and a CT scan showing probable pancreatic transection was done to define the extent and site of ductal injury. Identification of an intact ductal system permitted successful nonoperative therapy.

Thus, an emergency ERCP is proposed as the definitive test for pancreatic injury in patients in stable condition who do not require laparotomy for other reasons. Emergency ERCP is best done within 12 hours of injury since early treatment of confirmed pancreatic injuries reduces morbidity and mortality.[2] When laparotomy is performed for other injuries, intraoperative ERCP would define ductal anatomy without resorting to duodenotomy for ductography. Emergency preoperative ERCP or intraoperative ERCP is advocated in patients in stable condition with suspected pancreatic trauma.

ARCHIVES OF PATHOLOGY & LABORATORY MEDICINE

Expression of Pan-Neuroendocrine Proteins in 53 Neuroblastic Tumors: An Immunohistochemical Study With Neuron-Specific Enolase, Chromogranin, and Synaptophysin

Yoichi Hachitanda, MD; Masazumi Tsuneyoshi, MD; Munetomo Enjoji, MD

The presence and distribution of pan-neuroendocrine markers such as neuron-specific enolase (NSE), chromogranin (CG), and synaptophysin (SYP) were investigated by immunohistochemistry in 53 cases of neuroblastic tumors, including three cases of ganglioneuromas, 17 ganglioneuroblastomas, and 33 neuroblastomas. In ganglioneuromas, all three markers were observed both in ganglion cells and in neurofibrils. All cases of ganglioneuroblastoma were positive for these markers, however, some variability of staining intensity was noted. Of the 33 cases of neuroblastomas, all were positive for NSE, 23 (70%) for CG, and 31 (94%) for SYP. Neuron-specific enolase was detected not only in the majority of the neuroblasts showing signs of differentiation, but also in some undifferentiated neuroblasts. Chromogranin was found mainly in differentiated neuroblasts with enlarged cytoplasm and nuclei, but was scarcely found in undifferentiated cells. Synaptophysin was detected in some undifferentiated neuroblasts, as well as in differentiated neuroblasts. Two cases without SYP-positive cells were also negative for CG. Our observations conclude that antibodies against NSE and SYP are helpful as a diagnostic aid for neuroblastic tumors. (*Arch Pathol Lab Med.* 1989; 113:381-384).

Percutaneous Transhepatic Ultrasonic Cholelithotripsy

Anurag K. Das, MD; John L. Weinerth, MD; Steven C. Rose, MD; R. Randal Bollinger, MD, PhD

• In a patient with acute cholecystitis whose body habitus precluded cholecystectomy, we used percutaneous transhepatic ultrasonic cholelithotripsy. We compare it with other modalities applicable in such cases. Although not commonly used, these alternatives may be the most appropriate therapy in certain unusual circumstances.

(*Arch Surg* 1989;124:747-748)

In addition to the usual open surgical techniques, the treatment of renal calculi now includes various types of lithotripsy: extracorporeal shock wave, electrohydraulic, ultrasonic, and laser. These modalities can also be adapted to the treatment of gallstones, although most of the reported cases in the literature depict their use in the treatment of retained cystic duct and common bile duct stones. However, there has been limited experience in the fragmentation of gallstones by extracorporeal shock wave lithotripsy[1,2] and rapid dissolution of stones by instillation of methyl tert-butyl ether.[3] We present the use of percutaneous transhepatic ultrasonic cholelithotripsy in a patient whose body habitus precluded cholecystectomy or extracorporeal shock wave lithotripsy, and where stone calcium content did not allow dissolution.

REPORT OF A CASE

A 69-year-old man presented with an eight-day history of worsening epigastric and right-sided abdominal pain, fever, nausea, and vomiting. Medical history was remarkable for a coal-mining accident with "crush" injury to the spine resulting in disability due to severe kyphoscoliosis and hip angulation. Physical examination revealed an elderly man in moderate distress. The patient had a blood pressure of 110/70 mm Hg, respiratory rate of 24 breaths per minute, pulse of 100 beats per minute and regular, and temperature of 38.9° C. Abdominal examination revealed bilateral compression of the rib cage on the pelvis with almost no room between the right subcostal margin and the iliac crest. There was right-sided tenderness to palpation but no signs of peritoneal irritation. Laboratory studies revealed a white blood cell count of 11.6×10^9/L (normal, 4.5 to 10.5×10^9/L) with a left shift, normal hemoglobin level, normal serum chemistry results, aspartate aminotransferase level of 118 U/L (normal, 5 to 35 U/L), alanine aminotransferase level of 68 U/L (normal, 5 to 35 U/L), total bilirubin level of 22 μmol/L (normal, 3 to 21 μmol/L), and normal amylase level. An intravenous urogram was normal, and abdominal ultrasound revealed a 2-cm gallstone impacted at the cystic duct.

The patient was given intravenous antibiotics and transferred to our facility for further care. At our institution, abdominal computed tomography (Fig 1) revealed a thick-walled, dilated gallbladder, two gallstones with lamellated calcification (one impacted in the neck of the gallbladder and a second in the fundus), and pericholecystic fluid, all consistent with acute cholecystitis.

Since the patient's body habitus precluded a cholecystectomy, a percutaneous transhepatic 7.0F pigtail catheter was placed in the body of the gallbladder and 150 mL of purulent, sludge-laden bile was aspirated. A tube cholecystocholangiogram demonstrated two gallstones (2.5 and 1.0 cm in diameter). With the cholecystostomy tube left on external drainage, the patient was discharged for two weeks, then readmitted; he underwent dilation of the cholecystostomy tract with serial dilators with sheaths (Amplatz dilators) to 26F. A 24F Foley catheter and a 5F Kumpe catheter were then placed in the gallbladder through the Amplatz sheath. In addition, an 11.5-mm deflated venous occlusion balloon catheter was negotiated into the cystic duct (Fig 2).

Two days later the patient was taken to the operating room. Using general anesthesia, the Foley and Kumpe catheters were exchanged over heavy guide wires for a 26F Amplatz sheath. The cystic duct venous occlusion balloon catheter was inflated, and a

Fig 1.—Abdominal computed tomographic scan. Top, Near gallbladder fundus, at approximate level of subsequent percutaneous cholecystostomy; 1-cm lamellated calculus and thickened gallbladder wall (arrow). Bottom, Gallbladder neck with impacted 2.5-cm calcified calculus (arrow). Pericholecystic fluid present on sections between top and bottom.

Fig 2.—Lateral view cholecystogram before gallstone lithotripsy; patient's head to left. During catheter manipulations, calculus positions reversed such that 2.5-cm stone (white arrowhead) lies in gallbladder fundus and 1.0-cm stone (white arrow) resides near gallbladder neck; 24F Foley catheter (black arrowhead) and 5F Kumpe catheter (double black arrowhead) reside in gallbladder; venous occlusion balloon catheter (black arrows) is inflated with tip in cystic duct and guide wire into common bile duct and duodenum. Incidental electrocardiographic lead superiorly.

Fig 3.—True lateral view, cholecystogram following gallstone lithotripsy; 24F Foley catheter (black arrowhead) is inflated within gallbladder. Back-loaded 26F Amplatz sheath (white arrowhead) lies outside patient. No evidence of residual gallstones; free flow into common bile duct. No apparent biliary debris. Incidental film processor artifact (dark horizontal stripes).

24.5F Wolf nephroscope was placed in the gallbladder over a heavy guide wire. A 3.5-mm ultrasonic probe was then used to fragment the gallstones under direct vision, and the fragments were aspirated through the suction port. The procedure was uncomplicated. A 24F Foley catheter was left in the gallbladder for drainage. A tube cholecystocholangiogram on the second postoperative day (Fig 3) showed no retained fragments and free flow of contrast through the cystic and common bile ducts into the duodenum.

Before discharge on the fourth postoperative day, the 24F Foley catheter was exchanged for an 11F nephrostomy-type self-retaining catheter. One week later, a repeated tube cholecystocholangiogram was normal, and the cholecystostomy tube was removed. The patient remains asymptomatic and has a normal bilirubin level.

COMMENT

Cholecystectomy remains the accepted treatment of symptomatic cholelithiasis and cholecystitis. Percutaneous transhepatic electrohydraulic lithotripsy,[4] endoscopic mechanical and electrohydraulic lithotripsy,[5] and extracorporeal shock wave lithotripsy[6,7] have all been utilized in the treatment of retained cystic duct and common bile duct stones. In addition, Gacetta et al[8] reported two cases of ultrasonic lithotripsy of noncalcified gallstones after surgical cholecystostomy. These cases were done in a manner similar to ours except that the cystic duct was not occluded during the procedure.

Our patient's anatomy made it impossible to perform a cholecystectomy, and since the patient had percutaneous access, it was much easier to perform a percutaneous lithotripsy rather than to attempt a retrograde endoscopic procedure. The patient's anatomy also precluded extracorporeal shock wave lithotripsy on the Dornier HM-3 machine, and although the second-generation machines such as the Wolf Piezolith 2200 may not have been limited by the patient's anatomy, they are not used to treat calcified gallstones. Ultrasonic fragmentation of stones was chosen because the 3.5-mm hollow ultrasound probe allows suctioning capability, reducing the chance for small fragments to accumulate and possibly obstruct the cystic duct or the common bile duct ("steinstrasse" phenomenon, from the German word for street of stone).

Editorial Comment

This article is representative of a spate of reports that describe alternatives to cholecystectomy. In this instance, the patient's body habitus precluded cholecystectomy. The acute infection was treated by percutaneous cholecystostomy, which is being used experimentally in critically ill patients who develop acute cholecystitis after surgery or trauma or during another illness. The stones were fragmented by ultrasonic lithotripsy and removed by manual extraction. The authors discuss the currently available techniques for breaking up stones and removing them from the gallbladder. Although the treatment was effective in this unique circumstance, the report raises broader issues of importance to those who care for patients with biliary tract disease. Will one or a combination of high-technology procedures replace cholecystectomy for acute cholecystitis? Which procedure is safest and least troublesome for the patient? Changes in the management of biliary tract disease are inevitable because of the availability of these new techniques. Carefully designed, prospective studies must be done to determine the safest and most effective procedures. As surgeons, our skepticism is healthy, but we must not close our minds to the likelihood of change, and we must be at the forefront in conducting the necessary studies.

Argon Laser Treatment of Radiation Proctitis

John J. O'Connor, MD

• Radiation therapy for malignant gynecologic disease and prostatic cancer has resulted in increased survival and cure rates. This modality has unfortunately produced debilitating radiation proctitis. Recently, five patients were seen with continuous rectal bleeding secondary to radiation disease of the rectum. Four of these patients were women who were being treated for cervical carcinoma and one was a man with prostatic cancer. These patients were refractory to steroid retention enemas, iron therapy, and benproperine enema therapy. Treatment was accomplished using the argon laser with a 300-μm fiber passed via flexible fiberoptic sigmoidoscope. The most proximal areas were treated first. One and a half watts at 0.5 pulses was used. Up to 50 pulses were delivered per therapy session. The fiber was placed in contact with the lesion and circumferentially for 0.5 cm surrounding each suspected area. Bleeding stopped in the four women after two sessions and in the man after four sessions.
(*Arch Surg* 1989;124:749)

Radiation therapy for malignant gynecologic disease and prostatic cancer has resulted in increased survival and cure rates. This modality has unfortunately produced debilitating radiation proctitis. The bleeding that results from the proctitis can and does produce severe anemia that often requires replacement blood therapy. Recently, five patients were seen with continuous rectal bleeding secondary to radiation disease of the rectum. Four of these patients were women who were being treated for cervical carcinoma, and one was a man with prostatic cancer. These patients were refractory to steroid retention enemas, iron therapy, and benproperine enema therapy.

Three patients underwent endoscopy to ascertain the linear extent of the proctitis. Disease in all three patients was confined to the distal 30 cm of the colorectum. Treatment was accomplished using the argon laser with a 300-μm fiber passed via a flexible fiberoptic sigmoidoscope. The most proximal areas were treated first. One and a half watts at 0.5-s pulses was used. Up to 50 pulses were delivered per therapy session. The fiber was placed in contact with the lesion and circumferentially for 0.5 cm surrounding each suspected area.

Bleeding stopped in the four women after two sessions and in the man after four sessions. They were treated as outpatients, and did not require analgesic therapy. The patients have remained free of bleeding for five months without the use of medication.

The argon laser is well suited for the type of procedure performed on these patients. The vessels are superficial, requiring a 1- to 3-mm depth of coagulation and are usually small. Using telangiectasia as a model where the argon laser therapy is most effective, radiation proctitis should have a similar result.[1] These five cases seem to add proof to this hypothesis, at least in short-term follow-up. It seems that this method of coagulation could be used in the management of an ever-increasing group of patients.

Pain on Coughing and Numbness in Sciatica: What Exactly Do These Symptoms Mean?

To the Editor.—In sciatica, pain on coughing and segmental numbness are generally known symptoms. They are often mentioned in the literature, but their nature and clinical meaning have never been exactly defined. The new approach to the study of clinical findings in relation to disk changes, by lumbar diskography in our material,[1,2] has not been generally noticed and understood, and it is significant that 22 book reviews on the monograph,[2] in various journals, comment on the morphologic diagnosis but not on the analysis of the clinical findings.

Pain on coughing is found in disk rupture, the gelatinous contents of the nucleus pulposus being squeezed out of the disk to spread around the nerve root where they cause aseptic inflammation; it appears about one week after onset of the complaints. Numbness, however, is found in nerve compression, when a nonruptured disk exerts pressure to the root (these patients have no pain on coughing), or when particles of fibrous tissue dislocated through a disk rupture compress the root (with both numbness and pain on coughing present). This suggests that the clinical picture of sciatica is composed of two elements—the syndrome of nerve irritation (radiculitis) and the syndrome of nerve compression—or that there is a combination of both. The other symptoms and signs are nonspecific, but, in various forms of disk lesions, differ in intensity and persistence in the decourse of a case.

Pain on coughing can thus be defined as a symptom of radiculitis caused by disk rupture; treatment is conservative. Numbness is a symptom of nerve root compression in various forms of disk lesions, some of which may require surgical intervention. This knowledge, gained with the aid of diskography, contributes to a systematic evaluation of sciatica, without the need for diskography itself to be performed in the clinical routine. It seems justified to bring this to the attention of the clinic, as new detailed studies of the clinical picture in diskographic material are unlikely to appear, the attention of the clinic at present being turned to computerized tomography and nuclear magnetic resonance.

Away With Leniency Toward Gastric Pseudolymphoma

To the Editor.—Since its description in 1958, approximately 200 cases of gastric pseudolymphoma (GPL) have been reported. Gastric pseudolymphoma is regarded basically as a benign condition, although various authors have speculated on its potential for malignant transformation. Over the years, several reports associating GPL with malignant lymphoma have been published, thus implying that GPL may be a premalignant condition.[1-6] Nevertheless, to date, guidelines for treatment of GPL remain lenient.

Report of a Case.—We recently performed a subtotal gastrectomy on a 37-year-old woman who we had been observing for 20 years and in whom the diagnosis of GPL had been made, supported by repeated gastroscopic biopsy specimens. After many years of refusal, the patient finally agreed to undergo surgery, hoping to achieve the symptomatic relief that the numerous conservative treatments she had undergone had failed. At laparotomy, the gastric antrum was grossly thickened, and regional lymphadenopathy was noted. Histologic examination of the resected stomach revealed typical GPL (Figs 1 and 2), within which microscopic foci of malignant lymphoma (diffuse small cleaved cell type, poorly differentiated lymphocytic lymphoma) were detected (Figs 3 and 4). The regional lymph nodes showed reactive changes only.

Comment.—This is the 11th reported case, to our knowledge, associating GPL and malignant lymphoma. It is unique in that the histologic findings demonstrate the emergence of microscopic foci of malignant lymphoma within the bulky GPL, thus indicating malignant transformation in long-standing GPL.

Having recognized the premalignant potential of GPL, we believe that a change in our attitude toward this lesion and in the recommendations for its management is mandatory, and we suggest the following:

1. The data presented herein, together with those accumulated in the literature, strongly point to the affirmative resolution of the debate regarding the possibility of malignant transformation in GPL.
2. The true incidence of this malignant change remains unknown; data collected from the literature imply an incidence of roughly 5.5% (11/200 cases).
3. According to the data from the various cases, the lead time from the onset of symptoms to the occurrence of this malignant change differs within wide margins, but it may be as short as three months.
4. Contrary to the general concept in the literature, we believe that GPL may be diagnosed with near certainty by gastroscopic biopsy, provided that multiple deep biopsy specimens that include the submucosa are taken and cryostat immunoperoxidase studies are utilized.[7]
5. On the other hand, we presently have no absolutely reliable means for histologically monitoring GPL for the occurrence of malignant transformation, since the latter occurs in microscopic foci that are situated deep within the bulky GPL and give no corresponding changes on the mucosal surface that could help direct our bi-

Fig 1.—Transmural photomicrograph of gastric wall showing typical pseudolymphoma. Note numerous germinal centers (hematoxylin-eosin, original magnification ×40).

Fig 2.—Photomicrograph of lymphoid follicle with germinal center in lamina propria (hematoxylin-eosin, original magnification ×200).

Fig 3.—Photomicrograph of gastric wall implying transformation to focal gastric lymphoma. Note muscle-fiber destruction by lymphocytic infiltrate (hematoxylin-eosin, original magnification ×200).

Fig 4.—Photomicrograph of focus of malignant lymphoma within gastric pseudolymphoma. Note atypical lymphocytes with prominent nucleoli and pleomorphism (hematoxylin-eosin, original magnification ×1000).

opsy. Thus, although the lesion is readily accessible to repeated gastroscopic biopsies, these would be truly random biopsies and of doubtful credibility when the results are negative.

6. We believe that in the face of a less-than-optimal ability to monitor a premalignant lesion for occurrence of malignant transformation, there is a place for consideration of prophylactic resective surgery. In fact, in case of future malignant transformation with an unfavorable outcome, not having given the patient a clear presentation of the facts and an opportunity to consider the option of early surgery might even be regarded as negligent.

7. Accordingly, we believe that the traditionally lenient attitude toward GPL should be abandoned, and a more aggressive approach adopted. The above-mentioned facts should be clearly presented to patients, and the option for early gastric resection should be discussed. Ideally, the resection should be radical to the extent of removing all diseased tissue, but the surgical procedure should be tailored to the individual case (eg, to avoid the potential complications associated with an esophageal anastomosis in cases of GPL that involve the proximal stomach). Keeping in mind the possibility of lymphoma, preoperative and intraoperative staging measures are appropriate (eg, computed tomographic scans, bone marrow studies, and regional lymph node sampling/dissection).

Staple Line Healing in Gastric Surgery

To the Editor.—Dr Ravitch's reply to my communication[1,2] requires clarification.

I certainly do not feel that patients' behavior is to blame for leaks and perforations following bariatric surgery. However, their noncompliance may well be a factor in early, and possibly even late, staple line disruption after gastric partitioning. This is an entirely different situation. Leaks and perforations are life-threatening but staple line disruptions usually are not. A small disruption may only be apparent on upper gastrointestinal tract endoscopy or barium studies, but if the disruption is large, then gastric restriction will be lost. After a small disruption, the whole staple line could "unzip." If restriction is lost, the operation usually fails, particularly if this occurs in the early postoperative stage.

We know little about staple line healing in the morbidly obese human's stomach. If gastric restriction is going to be successful, even in carefully selected cases, knowledge of the time taken and the technique necessary to produce the strongest staple line possible is vitally important knowledge both for the bariatric surgeon and patient.

CEFOTAN® IM/IV (cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri,* and *Morganella morganii*).
Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.
Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis,** *Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.
Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis,** *Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).
Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).
Bone and joint infections caused by *Staphylococcus aureus.*†
***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.
† Efficacy for this organism in this organ system was studied in fewer than ten infections.
PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).
The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.
If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.
Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.
Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.
Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.
In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.
CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.
INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.
DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.
As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.
CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.
Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be

developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.
USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.
PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.
IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.
1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21).

Rocephin® ROCHE IV·IM

ceftriaxone sodium/Roche

Before prescribing, please consult complete product information, a summary of which follows:

INDICATIONS AND USAGE: Rocephin is indicated for the treatment of the following infections when caused by susceptible organisms:

LOWER RESPIRATORY TRACT INFECTIONS caused by *Strep. pneumoniae, Streptococcus* species (excluding enterococci), *Staph. aureus, H. influenzae, H. parainfluenzae, Klebsiella* species (including *K. pneumoniae*), *E. coli, E. aerogenes, Proteus mirabilis* and *Serratia marcescens*.

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus, Staph. epidermidis, Streptococcus* species (excluding enterococci), *E. cloacae, Klebsiella* species (including *K. pneumoniae*), *Proteus mirabilis* and *Pseudomonas aeruginosa*.

URINARY TRACT INFECTIONS (complicated and uncomplicated) caused by *E. coli, Proteus mirabilis, Proteus vulgaris, M. morganii* and *Klebsiella* species (including *K. pneumoniae*).

UNCOMPLICATED GONORRHEA (cervical/urethral and rectal) caused by *Neisseria gonorrhoeae*, including both penicillinase and nonpenicillinase producing strains.

PELVIC INFLAMMATORY DISEASE caused by *N. gonorrhoeae*.

BACTERIAL SEPTICEMIA caused by *Staph. aureus, Strep. pneumoniae, E. coli, H. influenzae* and *K. pneumoniae*.

BONE AND JOINT INFECTIONS caused by *Staph. aureus, Strep. pneumoniae, Streptococcus* species (excluding enterococci), *E. coli, P. mirabilis, K. pneumoniae* and *Enterobacter* species.

INTRA-ABDOMINAL INFECTIONS caused by *E. coli* and *K. pneumoniae*.

MENINGITIS caused by *H. influenzae, N. meningitidis* and *Strep. pneumoniae*. Ceftriaxone has also been used successfully in a limited number of cases of meningitis and shunt infections caused by *Staph. epidermidis* and *E. coli*.

SURGICAL PROPHYLAXIS: Preoperative administration of a single 1 gm dose may reduce incidence of postoperative infections in patients undergoing surgical procedures classified as contaminated or potentially contaminated (*e.g.*, vaginal or abdominal hysterectomy) and in those for whom infection at the operative site presents serious risk (*e.g.*, during coronary artery bypass surgery).

Although ceftriaxone has been shown to have been as effective as cefazolin in the prevention of infection following coronary artery bypass surgery, no placebo-controlled trials have been conducted to evaluate any cephalosporin antibiotic in the prevention of infection following coronary artery bypass surgery. When administered before indicated surgical procedures, a single 1 gm dose provides protection from most infections due to susceptible organisms for duration of procedure.

SUSCEPTIBILITY TESTING: Before instituting treatment with Rocephin, appropriate specimens should be obtained for isolation of the causative organism and for determination of its susceptibility to the drug. Therapy may be instituted prior to obtaining results of susceptibility testing.

CONTRAINDICATIONS: Rocephin is contraindicated in patients with known allergy to the cephalosporin class of antibiotics.

WARNINGS: BEFORE THERAPY WITH ROCEPHIN IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE WHETHER THE PATIENT HAS HAD PREVIOUS HYPERSENSITIVITY REACTIONS TO CEPHALOSPORINS, PENICILLINS OR OTHER DRUGS. THIS PRODUCT SHOULD BE GIVEN CAUTIOUSLY TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE THE USE OF SUBCUTANEOUS EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind to the toxin *in vitro*.

Mild cases of colitis respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte and protein supplementation as indicated.

When the colitis is not relieved by drug discontinuance or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C. difficile*. Other causes of colitis should also be considered.

Rarely, shadows suggesting sludge have been detected by sonograms of the gallbladder in asymptomatic and symptomatic patients. This appears to be reversible on discontinuation of therapy. In a few symptomatic patients receiving higher than usual doses, who underwent surgery, sludge containing traces of ceftriaxone was recovered from surgical specimens. Discontinue therapy in patients who develop signs or symptoms suggestive of gallbladder disease; consider conservative management.

PRECAUTIONS: *GENERAL:* Although transient elevations of BUN and serum creatinine have been observed, at the recommended dosages, the nephrotoxic potential of Rocephin is similar to that of other cephalosporins.

Ceftriaxone is excreted via both biliary and renal excretion (see Clinical Pharmacology). Therefore, patients with renal failure normally require no adjustment in dosage when usual doses of Rocephin are administered, but concentrations of drug in the serum should be monitored periodically. If evidence of accumulation exists, dosage should be decreased accordingly.

Dosage adjustments should not be necessary in patients with hepatic dysfunction; however, in patients with both hepatic dysfunction and significant renal disease, Rocephin dosage should not exceed 2 gm daily without close monitoring of serum concentrations.

Alterations in prothrombin times have occurred rarely in patients treated with Rocephin. Patients with impaired vitamin K synthesis or low vitamin K stores (*e.g.*, chronic hepatic disease and malnutrition) may require monitoring of prothrombin time during Rocephin treatment. Vitamin K administration (10 mg weekly) may be necessary if the prothrombin time is prolonged before or during therapy.

Prolonged use of Rocephin may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection occurs during therapy, appropriate measures should be taken.

Rocephin should be prescribed with caution in individuals with a history of gastrointestinal disease, especially colitis.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Carcinogenesis: Considering the maximum duration of treatment and the class of the compound, carcinogenicity studies with ceftriaxone in animals have not been performed. The maximum

ROCEPHIN® (ceftriaxone sodium/Roche)

duration of animal toxicity studies was six months.

Mutagenesis: Genetic toxicology tests included the Ames test, a micronucleus test and a test for chromosomal aberrations in human lymphocytes cultured *in vitro* with ceftriaxone. Ceftriaxone showed no potential for mutagenic activity in these studies.

Impairment of Fertility: Ceftriaxone produced no impairment of fertility when given intravenously to rats at daily doses up to 586 mg/kg/day, approximately 20 times the recommended clinical dose of 2 gm/day.

PREGNANCY: Teratogenic Effects: Pregnancy Category B. Reproductive studies have been performed in mice and rats at doses up to 20 times the usual human dose and have no evidence of embryotoxicity, fetotoxicity or teratogenicity. In primates, no embryotoxicity or teratogenicity was demonstrated at a dose approximately three times the human dose.

There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nonteratogenic Effects: In rats, in the Segment I (fertility and general reproduction) and Segment III (perinatal and postnatal) studies with intravenously administered ceftriaxone, no adverse effects were noted on various reproductive parameters during gestation and lactation, including postnatal growth, functional behavior and reproductive ability of the offspring, at doses of 586 mg/kg/day or less.

NURSING MOTHERS: Low concentrations of ceftriaxone are excreted in human milk. Caution should be exercised when Rocephin is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness of Rocephin in neonates, infants and children have been established for the dosages described in the Dosage and Administration section. *In vitro* studies have shown ceftriaxone, like some other cephalosporins, can displace bilirubin from serum albumin. Exercise caution before administration to hyperbilirubinemic neonates, especially prematures.

ADVERSE REACTIONS: Rocephin is generally well tolerated. In clinical trials, the following adverse reactions, which were considered to be related to Rocephin therapy or of uncertain etiology, were observed:

LOCAL REACTIONS—pain, induration or tenderness at the site of injection (1%). Less frequently reported (less than 1%) was phlebitis after I.V. administration.

HYPERSENSITIVITY—rash (1.7%). Less frequently reported (less than 1%) were pruritus, fever or chills.

HEMATOLOGIC—eosinophilia (6%), thrombocytosis (5.1%) and leukopenia (2.1%). Less frequently reported (less than 1%) were anemia, neutropenia, lymphopenia, thrombocytopenia and prolongation of the prothrombin time.

GASTROINTESTINAL—diarrhea (2.7%). Less frequently reported (less than 1%) were nausea or vomiting, and dysgeusia.

HEPATIC—elevations of SGOT (3.1%) or SGPT (3.3%). Less frequently reported (less than 1%) were elevations of alkaline phosphatase and bilirubin.

RENAL—elevations of the BUN (1.2%). Less frequently reported (less than 1%) were elevations of creatinine and the presence of casts in the urine.

CENTRAL NERVOUS SYSTEM—headache or dizziness were reported occasionally (less than 1%).

GENITOURINARY—moniliasis or vaginitis were reported occasionally (less than 1%).

MISCELLANEOUS—diaphoresis and flushing were reported occasionally (less than 1%).

Other rarely observed adverse reactions (less than 0.1%) include leukocytosis, lymphocytosis, monocytosis, basophilia, a decrease in the prothrombin time, jaundice, gallbladder sludge, glycosuria, hematuria, anaphylaxis, bronchospasm, serum sickness, abdominal pain, colitis, flatulence, dyspepsia, palpitations and epistaxis.

DOSAGE AND ADMINISTRATION: Rocephin may be administered intravenously or intramuscularly. The usual adult daily dose is 1 to 2 gm given once a day (or in equally divided doses twice a day) depending on the type and severity of the infection. The total daily dose should not exceed 4 grams.

For the treatment of serious miscellaneous infections in children, other than meningitis, the recommended total daily dose is 50 to 75 mg/kg (not to exceed 2 grams), given in divided doses every 12 hours.

Generally, Rocephin therapy should be continued for at least two days after the signs and symptoms of infection have disappeared. The usual duration is 4 to 14 days; in complicated infections longer therapy may be required.

In the treatment of meningitis, a daily dose of 100 mg/kg (not to exceed 4 grams), given in divided doses every 12 hours, should be administered with or without a loading dose of 75 mg/kg.

For the treatment of uncomplicated gonococcal infections, a single intramuscular dose of 250 mg is recommended.

For preoperative use (surgical prophylaxis), a single dose of 1 gm administered 1/2 to 2 hours before surgery is recommended.

When treating infections caused by *Streptococcus pyogenes*, therapy should be continued for at least ten days.

No dosage adjustment is necessary for patients with impairment of renal or hepatic function; however, blood levels should be monitored in patients with severe renal impairment (*e.g.*, dialysis patients) and in patients with both renal and hepatic dysfunctions.

HOW SUPPLIED: Rocephin (ceftriaxone sodium/Roche) is supplied as a sterile crystalline powder in glass vials and piggyback bottles. The following packages are available:

Vials containing 250 mg, 500 mg, 1 gm or 2 gm equivalent of ceftriaxone; piggyback bottles containing 1 gm or 2 gm equivalent of ceftriaxone; bulk pharmacy containers containing 10 gm equivalent of ceftriaxone (NOT FOR DIRECT ADMINISTRATION).

Also supplied as a sterile crystalline powder as follows:

ADD-Vantage Vials** containing 1 gm or 2 gm equivalent of ceftriaxone.

Also supplied premixed as a frozen iso-osmotic, sterile, nonpyrogenic solution of ceftriaxone sodium in 50 mL single dose plastic containers,† as follows:

1 gm equivalent of ceftriaxone, iso-osmotic with approximately 1.9 gm dextrose hydrous, USP added.

2 gm equivalent of ceftriaxone, iso-osmotic with approximately 1.2 gm dextrose hydrous, USP added.

NOTE: Rocephin in the frozen state should not be stored above -20°C.

GENERAL SURGEON

General Surgeon needed now for a respected multi-specialty group practice in Kentucky. The group serves a well-staffed and equipped, JCAH accredited community hospital, which is immediately adjacent to the modern clinic facility. The hospital includes a 30-bed skilled nursing unit.

Set in the rolling hills of central Kentucky, it is within 1 hour of a metropolitan area, major college sports, 8 large parks and one of the largest and most beautiful lakes in the nation. The cost of living is well below the national average.

The financial package offered is very competitive and includes a guaranteed salary and a full range of benefits including malpractice insurance. Full partnership will be offered after the satisfactory completion of 2 years.

For information, please call Consultant Judy Barnes at 1-800-283-6287, or send your curriculum vitae in confidence to her attention at Focus: HealthCare, 129 North Adams Street, Louisville, Kentucky 40206.

FOCUS: healthcare

GENERAL SURGEON
SAN FRANCISCO BAY AREA

Outstanding opportunity for BE/BC general surgeon starting July, 1989. Interesting surgical practice in a beautiful area to live and work. Excellent salary and exceptional benefits, with opportunity to become shareholder in two years and senior partner in three years. Direct inquiries to:

Chief, Department of Surgery
Kaiser Permanente Medical Center
1150 Veterans Blvd.
Redwood City, CA 94063

vicodin®

(hydrocodone bitartrate 5mg [Warning: May be habit forming] and acetaminophen 500 mg)

vicodin ES®

(hydrocodone bitartrate 7.5mg [Warning: May be habit forming] and acetaminophen 750 mg)

INDICATIONS AND USAGE: For the relief of moderate to moderately severe pain.

CONTRAINDICATIONS: Hypersensitivity to acetaminophen or hydrocodone.

WARNINGS:

Allergic-Type Reactions: VICODIN/VICODIN ES Tablets contain sodium metabisulfite, a sulfite that may cause allergic-type reactions including anaphylactic symptoms and life-threatening or less severe asthmatic episodes in certain susceptible people.

Respiratory Depression: At high doses or in sensitive patients, hydrocodone may produce dose-related respiratory depression.

Head Injury and Increased Intracranial Pressure: The respiratory depressant effects of narcotics and their capacity to elevate cerebrospinal fluid pressure may be markedly exaggerated in the presence of head injury, other intracranial lesions or a preexisting increase in intracranial pressure. Furthermore, narcotics produce adverse reactions which may obscure the clinical course of patients with head injuries.

Acute Abdominal Conditions: The administration of narcotics may obscure the diagnosis or clinical course of patients with acute abdominal conditions.

PRECAUTIONS:

Special Risk Patients: VICODIN/VICODIN ES Tablets should be used with caution in elderly or debilitated patients and those with severe impairment of hepatic or renal function, hypothyroidism, Addison's disease, prostatic hypertrophy or urethral stricture.

Cough Reflex: Hydrocodone suppresses the cough reflex; as with all narcotics, caution should be exercised when VICODIN/VICODIN ES Tablets are used postoperatively and in patients with pulmonary disease.

Drug Interactions: Patients receiving other narcotic analgesics, antipsychotics, antianxiety agents, or other CNS depressants (including alcohol) concomitantly with VICODIN/VICODIN ES Tablets may exhibit an additive CNS depression. The use of MAO inhibitors or tricyclic antidepressants with hydrocodone preparations may increase the effect of either the antidepressant or hydrocodone. The concurrent use of anticholinergics with hydrocodone may produce paralytic ileus.

Usage in Pregnancy:

Teratogenic Effects: Pregnancy Category C. Hydrocodone has been shown to be teratogenic in hamsters when given in doses 700 times the human dose. There are no adequate and well-controlled studies in pregnant women. VICODIN/ VICODIN ES Tablets should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nonteratogenic effects: Babies born to mothers who have been taking opioids regularly prior to delivery will be physically dependent. The withdrawal signs include irritability and excessive crying, tremors, hyperactive reflexes, increased respiratory rate, increased stools, sneezing, yawning, vomiting, and fever.

Labor and Delivery: Administration of VICODIN/VICODIN ES Tablets to the mother shortly before delivery may result in some degree of respiratory depression in the newborn, especially if higher doses are used.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions in nursing infants from VICODIN/VICODIN ES Tablets, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS:

The most frequently observed adverse reactions include light-headedness, dizziness, sedation, nausea and vomiting. These effects seem to be more prominent in ambulatory than in nonambulatory patients and some of these adverse reactions may be alleviated if the patient lies down. Other adverse reactions include:

Central Nervous System: Drowsiness, mental clouding, lethargy, impairment of mental and physical performance, anxiety, fear, dysphoria, psychic dependence and mood changes.

Gastrointestinal System: The antiemetic phenothiazines are useful in suppressing the nausea and vomiting which may occur (see above); however, some phenothiazine derivatives seem to be antianalgesic and to increase the amount of narcotic required to produce pain relief, while other phenothiazines reduce the amount of narcotic required to produce a given level of analgesia. Prolonged administration of VICODIN/VICODIN ES Tablets may produce constipation.

Genitourinary System: Ureteral spasm, spasm of vesical sphincters and urinary retention have been reported.

Respiratory Depression: Hydrocodone bitartrate may produce dose-related respiratory depression by acting directly on the brain stem respiratory center. Hydrocodone also affects the center that controls respiratory rhythm, and may produce irregular and periodic breathing. If significant respiratory depression occurs, it may be antagonized by the use of naloxone hydrochloride. Apply other supportive measures when indicated.

DRUG ABUSE AND DEPENDENCE:

VICODIN/VICODIN ES Tablets are subject to the Federal Controlled Substance Act (Schedule III). Psychic dependence, physical dependence, and tolerance may develop upon repeated administration of narcotics; therefore, VICODIN/ VICODIN ES Tablets should be prescribed and administered with caution.

OVERDOSAGE:

Acetaminophen Signs and Symptoms: In acute acetaminophen overdosage, dose-dependent, potentially fatal hepatic necrosis is the most serious adverse effect. Renal tubular necrosis, hypoglycemic coma, and thrombocytopenia may also occur. Early symptoms following a potentially hepatotoxic overdose may include: nausea, vomiting, diaphoresis and general malaise. Clinical and laboratory evidence of hepatic toxicity may not be apparent until 48 to 72 hours post-ingestion.

Hydrocodone Signs and Symptoms: Serious overdose with hydrocodone is characterized by respiratory depression (a decrease in respiratory rate and/or tidal volume, Cheyne-Stokes respiration, (cyanosis), extreme somnolence progressing to stupor or coma, skeletal muscle flaccidity, cold and clammy skin, and sometimes bradycardia and hypotension. In severe overdosage, apnea, circulatory collapse, cardiac arrest and death may occur.

PAPERS READ BEFORE THE 96TH ANNUAL MEETING OF THE WESTERN SURGICAL ASSOCIATION, SAN DIEGO, CALIF, NOV 14-16, 1988

They Call It Competition: Presidential Address . . . 771
Melvin A. Block, MD, PhD, La Jolla, Calif

An Analysis of the Reduced Morbidity and Mortality Rates After Pancreaticoduodenectomy . . . 778
Carlos A. Pellegrini, MD; Christopher F. Heck, MD; Steven Raper, MD; Lawrence W. Way, MD, San Francisco, Calif
• Computed tomographic scan preoperative assessment combined with improved operative technique has lowered the mortality rate associated with the Whipple procedure.

Percutaneous Cholecystostomy in the Diagnosis and Treatment of Acute Cholecystitis in the High-Risk Patient . . . 782
Gordon B. Werbel, MD; David L. Nahrwold, MD; Raymond J. Joehl, MD; Robert L. Vogelzang, MD; Robert V. Rege, MD, Chicago, Ill
• Percutaneous cholecystostomy and bile cultures in critically ill patients can avoid the excessive risk of cholecystectomy.

Endoscopic Cholangiography and Stone Removal Prior to Cholecystectomy: A More Cost-effective Approach Than Operative Duct Exploration? . . . 787
Greg Van Stiegmann, MD; Nathan W. Pearlman, MD; John S. Goff, MD; John H. Sun, MD; Lawrence W. Norton, MD, Denver, Colo
• Patients requiring cholecystectomy with suspected choledocholithiasis may be treated more cost effectively by ERCP with common duct stone removal prior to cholecystectomy than by cholecystectomy and common duct exploration.

Less Is Better: The Diagnostic Workup of the Patient With Obstructive Jaundice . . . 791
Richard Olen, MD; Jack Pickleman, MD; Robert J. Freeark, MD, Maywood, Ill
• If an abdominal ultrasound study in the typical patient with obstructive jaundice discloses distal bile duct obstruction, no further tests are necessary.

Function of Pancreas Allografts More Than 1 Year Following Transplantation . . . 796
Francis H. Wright, MD; John L. Smith, MD; Scott A. Ames, MD; Barbara Schanbacher, RN; Robert J. Corry, MD, Iowa City, Iowa
• Pancreatic transplantation achieves a euglycemic state in type I diabetes mellitus patients but warrants a long-term follow-up.

Changes in Tibial Venous Blood Flow in the Evolving Compartment Syndrome . . . 801
William G. Jones II, MD; Malcolm O. Perry, MD; Harry L. Bush, Jr, MD, New York, NY
• Interference with tibial venous blood flow is an early event with increased muscle compartment pressures and can be followed up with Doppler venous flow evaluation.

Myocardial Contusion: When Can the Diagnosis Be Eliminated? . . . 805
Frank B. Miller, MD; Charles R. Shumate, MD; J. David Richardson, MD, Louisville, Ky
• The electrocardiogram and the clinical course were the primary determinants of the need for cardiac monitoring and therapeutic intervention.

Intra-abdominal Injury Following Blunt Trauma: Identifying the High-Risk Patient Using Objective Risk Factors . . . 809
Robert C. Mackersie, MD; Anurag D. Tiwary, MD; Steven R. Shackford, MD; David B. Hoyt, MD, San Diego, Calif
• Of 11 clinical indicators assessed, arterial base deficit, major chest injury, hypotension, and pelvic fractures significantly increased the chance of intra-abdominal injury.

The **ARCHIVES OF SURGERY** (ISSN 0004-0010) is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago, IL 60610, and at additional mailing office.

SUBSCRIPTION RATES—The subscription rates for the ARCHIVES OF SURGERY are as follows: $50 for one year, $85 for two years in the United States and US possessions; all other countries, one year, $60; two years, $105 for surface delivery. (For expedited air delivery to most countries, add $15 surcharge for one year subscription, $30 for two years.) Rates for subscriptions for delivery to Japan or South Korea are available through exclusive agents—contact the publisher. ***Special rates for residents and medical students in the United States and US Possessions are available.*** Address inquiries to the American Medical Association, Circulation and Fulfillment Division, 535 N Dearborn St, Chicago, IL 60610. Phone: (312)280-7168.

CHANGE OF ADDRESS—POSTMASTER, send all address changes to the ARCHIVES OF SURGERY, Attention: Subscription Department, 535 N Dearborn St, Chicago, IL 60610. Notification of address change must be made at least six weeks in advance, include both old and new addresses, a recent mailing label, and your new zip code.

CONTENTS—Continued

Fine-Needle Aspiration for Breast Mass Diagnosis 814
William H. Wolberg, MD; Martin A. Tanner, PhD; Wei-Yin Loh, PhD, Madison, Wis
• A statistically based algorithm for fine-needle biopsy of breast masses reveals clinical parameters with a sensitivity of 0.98, a specificity of 0.94 and a positive predictability of 0.92

Oncological Aspects of Immediate Breast Reconstruction Following Mastectomy for Malignancy 819
Craig H. Johnson, MD; Jon A. van Heerden, MB, FRCSC; John H. Donohue, MD, Rochester, Minn; J. Kirk Martin, Jr, MD, Jacksonville, Fla; Ian T. Jackson, MD, FRCS(Glasg), FRCS(Edin), Duane M. Ilstrup, MS, Rochester, Minn
• Immediate breast reconstruction should be offered women with operable breast cancer because of the positive psychosocial benefit without a negative impact on patient outcome

The Outcome Index: A Method of Quality Assurance in the Special Care Area 825
Arthur S. McFee, MD, James Gilbert, MD, San Antonio, Tex
• A system outcome score (SOS) is suggested as a method of quality assurance for the surgical intensive care unit.

Nonoperative Treatment of Perforated Duodenal Ulcer 830
Thomas V. Berne, MD, Arthur J. Donovan, MD, Los Angles, Calif
• The perforated duodenal ulcer can be treated nonoperatively when a gastroduodenogram documents self-sealing.

Catheter Aspiration for Simple Pneumothorax: Experience with 114 Patients 833
Ralph E. Delius, MD; Farouck N. Obeid, MD; H. Mathilda Horst, MD; Victor J. Sorensen, MD; John J. Fath, MD; Brack A. Bivins, MD, Detroit, Mich
• Catheter aspiration is a safe, successful, and cost-effective technique for managing the simple pneumothorax.

Changing Patterns of Treatment and Survival in Neonates With Meconium Ileus 837
Frederick J. Rescorla, MD; Jay L. Grosfeld, MD; Karen J. West, MD; Dennis W. Vane, MD, Indianapolis, Ind
• Nonoperative technique can relieve obstruction in uncomplicated meconium ileus and avoid enterostomy in most cases.

Medullary Carcinoma in Children: Results of Early Detection and Surgery 841
Robert L. Telander, MD; Donald Zimmerman, MD; Glen W. Sizemore, MD; Jon A. van Heerden, MB, ChB; Clive S. Grant, MD, Rochester, Minn
• All children with multiple endocrine neoplasia type IIb (MEN-IIb) should be studied shortly after birth, and those with MEN-IIa should be studied by 1 year of age.

ORIGINAL ARTICLES

Evaluation Of Staging Workup in Malignant Melanoma 847
Tawfiq Khansur, MD; Jane Sanders, MD; Suman K. Das, MD, Jackson, Miss
• There is no need for routine work-up for metastases in malignant melanoma unless the serum LDH is elevated

Early Detection of Shock in Critically Ill Patients by Skeletal Muscle Po_2 Assessment 853
Gerald I. J. M. Beerthuizen, MD; R. Jan A. Goris, MD; Ferdinand J. A. Kreuzer, PhD, Nijmegen, the Netherlands
• Skeletal muscle Po_2 helped predict the development of shock if inotropic agents had not been given.

Oxidative Activity of Polymorphonuclear Leukocytes After Thermal Injury 856
Marek K. Dobke, MD, PhD; Edwin A. Deitch, MD; Timothy J. Harnar, MD; Charles R. Baxter, MD, Lubbock, Tex
• Neutrophils from burn patients have increased resting and decreased zymosan-stimulated oxygen consumption when compared with neutrophils of control patients.

Posttraumatic Autotransplantation of Spleen Tissue 863
Solly Mizrahi, MD; Amitai Bickel, MD; Mahmud Haj, MD; Ida Lunski, MD; Benjamin Shtamler, MD, Nahariya, Israel
• Following splenectomy for trauma, spleen tissue was successfully autotransplanted in patients

Recurrent Stenosis by Duplex Scan Following Carotid Endarterectomy 866
Vincent J. Bertin, MD; Fred R. Plecha, MD; Gregory J. Rogers, MD; Karen MacPherson, RNC; Judith Lund, LPN, Cleveland, Ohio
• Following carotid endarterectomy a higher incidence of recurrent stenosis was found in female patients.

CLINICAL NOTES

Primary Aortoduodenal Fistula: Diagnosis by Computed Tomography 870
Ibrahim M. Ibrahim, MD, Joseph S. Raccuia, MD, Englewood, NJ; Joseph Micale, MD, Asham Zafar, MD, North Bergen, NJ
• A computed tomographic scan aided in the preoperative diagnosis of abdominal aortic aneurysm with duodenal fistula.

Hernia Uterus Inguinale Associated With Unicornuate Uterus 872
David C. Elliott, MD; Thomas E. Beam, MD; Thomas S. Denapoli, MD, Washington, DC
• An incarcerated inguinal hernia contained an ovary, a fallopian tube, and a rudimentary uterine horn.

TECHNIQUE

A New Surgical Localization Technique for Biopsy in Patients With Nipple Discharge 874
Arindam Choudhury, MD, Paul A. Wengert, Jr, MD, Harrisburg, Pa; J. Stanley Smith, Jr, MD, Hershey, Pa
• Dye injection localization was used during operative treatment of nipple discharge.

COBE *BRAT*™—The fastest, most versatile way to meet all of your autologous blood salvage demands.

When surgeons wanted maximum speed in RBC turnaround, they developed their own autotransfusion system. Then perfected it at the Baylor College of Medicine and the Methodist Hospital in Houston. And to ensure its versatility in all types of procedures, they turned to COBE/Kardiothor.

The unique BRAT (Baylor Rapid Autologous Transfusion) System gives you more RBCs faster. When you need them most. In major trauma, open heart, vascular, and emergency procedures.

Its innovative centrifuge bowl design provides consistently higher hematocrits (averaging more than 50%) and excellent heparin removal. Plus, a special, built-in reinfusion protection system provides an added measure of safety during use, allowing *reinfusion under pressure in critical situations.*

Maybe that's why the BRAT autotransfusion system is *the* choice among surgeons at major medical centers today. And why the BRAT offers the RBC quality, speed, and versatility of an autotransfusion system you might have designed yourself.

For more information, call *1-800-622-BRAT* or *1-800-525-COBE.*

O.R. clutter.

The obstacle course of the surgical team. Great for the funhouse, but in life or death, it's no laughing matter.

Our equipment and systems have been at the core of surgical suites for decades. And we've learned to think like a team member.

Today our experience is helping you move better and stand easier during most procedures.

We have designs on the O.R. that put things where you need them, and let you concentrate on why you're really there.

AMSCO
Right from the start

WHY NOT TAKE EARLY AMBULATION A STEP FURTHER?

You can get patients moving even before they can walk...with Kinetic Therapy℠

Kinetic Therapy,℠ as furnished by the BioDyne™ bed, uses continuous oscillation on an air-support surface to bring motion to patients unable to move on their own. Consider postoperative patients. Those immobilized by surgery urgently need the mechanical stimulation of natural motion.

Kinetic Therapy on the BioDyne bed provides early intervention and treatment of immobility—without waiting for complications to develop. By gently turning patients from side to side, it promotes continuous postural drainage, helps minimize venous stasis, and helps prevent skin ischemia and breakdown.

Just like early ambulation... only sooner.

BioDyne™ II

Because Life Depends on Motion

RED ZONE:

Gram-Negative Alert

In patients who are

- intubated
- immuno-compromised
- catheterized
- elderly
- multiply-hospitalized

THE RATIONAL CHOICE:

FORTAZ® IV/IM

ceftazidime/Glaxo

1 g vials 1-2 g q8-12h

For empiric therapy of suspected gram-negative infection*

- Highly effective against a broad spectrum of pathogens from gram-negative *Pseudomonas* and the Enterobacteriaceae to gram-positive staphylococci
- As effective as the aminoglycosides, without exposing the patient to possible aminoglycoside toxicity
- Well tolerated...safety profile similar to that of the first-generation cephalosporins*
- Proven performance in over 3 years of worldwide experience

*Please see Brief Summary of Prescribing Information on next page for a full listing of indications, susceptible organisms, and adverse reactions.

Glaxo pioneers in cephalosporin research
Glaxo Inc., Research Triangle Park, NC 27709

FOR 194

FORTAZ®
ceftazidime for injection

For intravenous or intramuscular use

Brief summary. Before prescribing, consult complete prescribing information.

INDICATIONS AND USAGE

FORTAZ® is indicated for the treatment of patients with infections caused by susceptible strains of the designated organisms in the following diseases:

1. **Lower Respiratory Tract Infections**, including pneumonia, caused by *P aeruginosa* and other *Pseudomonas* sp; *H influenzae*, including ampicillin-resistant strains; *Klebsiella* sp; *Enterobacter* sp; *P mirabilis*; *E coli*; *Serratia* sp; *Citrobacter* sp; *S pneumoniae*; and *S aureus* (methicillin-susceptible strains).
2. **Skin and Skin Structure Infections** caused by *P aeruginosa*; *Klebsiella* sp; *E coli*; *Proteus* sp, including *P mirabilis* and indole-positive *Proteus*; *Enterobacter* sp; *Serratia* sp; *S aureus* (methicillin-susceptible strains); and *S pyogenes* (group A beta-hemolytic streptococci).
3. **Urinary Tract Infections**, both complicated and uncomplicated, caused by *P aeruginosa*; *Enterobacter* sp; *Proteus* sp, including *P mirabilis* and indole-positive *Proteus*; *Klebsiella* sp; and *E coli*.
4. **Bacterial Septicemia**, caused by *Paeruginosa*; *Klebsiella* sp; *H influenzae*; *E coli*; *Serratia* sp; *S pneumoniae*; and *S aureus* (methicillin-susceptible strains).
5. **Bone and Joint Infections**, caused by *P aeruginosa*; *Klebsiella* sp; *Enterobacter* sp; and *S aureus* (methicillin-susceptible strains).
6. **Gynecological Infections**, including endometritis, pelvic cellulitis, and other infections of the female genital tract, caused by *E coli*.
7. **Intra-abdominal Infections**, including peritonitis, caused by *E coli*, *Klebsiella* sp, and *S aureus* (methicillin-susceptible strains) and polymicrobial infections caused by aerobic and anaerobic organisms and *Bacteroides* sp (many strains of *B fragilis* are resistant).
8. **Central Nervous System Infections**, including meningitis, caused by *H influenzae* and *Neisseria meningitidis*. FORTAZ has also been used successfully in a limited number of cases of meningitis due to *P aeruginosa* and *S pneumoniae*.

Specimens for bacterial cultures should be obtained prior to therapy in order to isolate and identify causative organisms and to determine their susceptibility to ceftazidime. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.

FORTAZ may be used alone in cases of confirmed or suspected sepsis. FORTAZ has been used successfully in clinical trials as empiric therapy in cases where various concomitant therapies with other antibiotics have been used.

FORTAZ may also be used concomitantly with other antibiotics, such as aminoglycosides, vancomycin, and clindamycin, in severe and life-threatening infections and in the immunocompromised patient. When such concomitant treatment is appropriate, prescribing information in the labeling for the other antibiotics should be followed. The dose depends on the severity of the infection and the patient's condition.

CONTRAINDICATIONS

FORTAZ® is contraindicated in patients who have shown hypersensitivity to ceftazidime or the cephalosporin group of antibiotics.

WARNINGS

BEFORE THERAPY WITH FORTAZ® IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE WHETHER THE PATIENT HAS HAD PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFTAZIDIME, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. THIS PRODUCT SHOULD BE GIVEN WITH CAUTION TO PATIENTS WITH TYPE 1 HYPERSENSITIVITY REACTIONS TO PENICILLIN. IF AN ALLERGIC REACTION TO FORTAZ OCCURS, DISCONTINUE TREATMENT WITH THE DRUG. SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics alters normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *C difficile* is one primary cause of antibiotic-associated colitis.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated.

When the colitis is not relieved by drug discontinuance or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes of colitis should also be considered.

PRECAUTIONS

FORTAZ® has not been shown to be nephrotoxic; however, because high and prolonged serum antibiotic concentrations can occur from usual doses in patients with transient or persistent reduction of urinary output because of renal insufficiency, the total daily dosage should be reduced when ceftazidime is administered to such patients (see **DOSAGE AND ADMINISTRATION**). Continued dosage should be determined by degree of renal impairment, severity of infection, and susceptibility of the causative organisms.

As with other antibiotics, prolonged use of FORTAZ may result in overgrowth of nonsusceptible organisms. Repeated evaluation of the patient's condition is essential. If superinfection occurs during therapy, appropriate measures should be taken.

FORTAZ should be prescribed with caution in individuals with a history of gastrointestinal disease, particularly colitis.

Drug Interactions: Nephrotoxicity has been reported following concomitant administration of cephalosporins with aminoglycoside antibiotics or potent diuretics such as furosemide. Renal function should be carefully monitored, especially if higher dosages of the aminoglycosides are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Nephrotoxicity and ototoxicity were not noted when FORTAZ was given alone in clinical trials.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have not been performed to evaluate carcinogenic potential. However, a mouse Micronucleus test and an Ames test were both negative for mutagenic effects.

Pregnancy: ***Teratogenic Effects: Pregnancy Category B:*** Reproduction studies have been performed in mice and rats at doses up to 40 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to FORTAZ. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: Ceftazidime is excreted in human milk in low concentrations. Caution should be exercised when FORTAZ is administered to a nursing woman.

ADVERSE REACTIONS

FORTAZ® is generally well tolerated. The incidence of adverse reactions associated with the administration of FORTAZ was low in clinical trials. The most common were local reactions following intravenous injection and allergic and gastrointestinal reactions. Other adverse reactions were encountered infrequently. No disulfiram-like reactions were reported.

The following adverse effects from clinical trials were considered to be either related to ceftazidime therapy or were of uncertain etiology:

Local Effects, reported in less than 2% of patients, were phlebitis and inflammation at the site of injection (1 in 69 patients).

Hypersensitivity Reactions, reported in 2% of patients, were pruritus, rash, and fever. Immediate hypersensitivity reactions occurred in 1 in 285 patients.

Gastrointestinal Symptoms, reported in less than 2% of patients, were diarrhea (1 in 78), nausea (1 in 156), vomiting (1 in 500), and abdominal pain (1 in 416).

Less Frequent Adverse Events (less than 1%) were candidiasis; vaginitis; and central nervous system events that included headache, dizziness, and paresthesia.

Laboratory Test Changes noted during FORTAZ clinical trials were transient and included: eosinophilia (1 in 13), positive Coombs' test without hemolysis (1 in 23), thrombocytosis (1 in 45), and slight elevations in one or more of the hepatic enzymes, SGOT (1 in 16), SGPT (1 in 15), LDH (1 in 18), GGT (1 in 19), and alkaline phosphatase (1 in 23). As with some other cephalosporins, transient elevations of blood urea, blood urea nitrogen and/or serum creatinine were observed occasionally. Transient leukopenia, neutropenia, thrombocytopenia and lymphocytosis were seen very rarely.

DOSAGE AND ADMINISTRATION

Impaired Renal Function: Ceftazidime is excreted by the kidneys, almost exclusively by glomerular filtration. Therefore, in patients with impaired renal function (GFR < 50 ml/min), it is recommended that the dosage of ceftazidime be reduced to compensate for its slower excretion. See complete Prescribing Information for dosage in patients with renal impairment.

HOW SUPPLIED

FORTAZ® in the dry state should be stored at controlled room temperature, 15° to 30°C (59° to 86°F), and protected from light. FORTAZ is a dry, white to off-white powder supplied in vials and infusion packs as follows:

NDC 0173-0377-31 500-mg* Vials (Tray of 25)
NDC 0173-0378-35 1-g* Vials (Tray of 25)
NDC 0173-0379-34 2-g* Vials (Tray of 10)
NDC 0173-0380-32 1-g* Infusion Pack (Tray of 10)
NDC 0173-0381-32 2-g* Infusion Pack (Tray of 10)
NDC 0173-0382-37 6-g* Pharmacy Bulk Package (Tray of 6)

*Equivalent to anhydrous ceftazidime.

Now available from Elsevier!
The Annals of Thoracic Surgery

Official Journal of The Society of Thoracic Surgeons and the Southern Thoracic Surgical Association

Editor: **Thomas B. Ferguson, M.D.,**
Barnes Hospital, St. Louis, MO

For 25 years, **The Annals of Thoracic Surgery** has provided outstanding original coverage of recent progress in chest and cardiovascular surgery and related fields. A forum for the exchange of knowledge and ideas for all thoracic surgeons, this timely journal features case reports, "How To Do It" articles, collective reviews, book reviews, editorials, letters to the editor, and supplements for symposia.

Authoritative — As the official journal of The Society of Thoracic Surgeons and the Southern Thoracic Surgical Association, **The Annals** enjoys outstanding editorial leadership and maintains rigorous selection standards.

Clinically Oriented — If you're the kind of professional who's always looking for improved techniques that will make life easier for your patients (and yourself), **The Annals of Thoracic Surgery** is ideally suited to help you.

Comprehensive — As a subscriber, you'll enjoy not only timely articles dealing with conditions of the heart, lungs, esophagus, and great vessels, but also research papers on a wide variety of related thoracic and cardiovascular topics.

1989 Subscription Information, Volumes 47, 48 (12 issues)

W. Dean Warren, MD

October 28, 1924–May 10, 1989

On May 10, 1989, one of the "best and brightest" men in this noble profession died. W. Dean Warren, MD, the Joseph Brown Whitehead Professor and Chairman of Surgery at Emory University School of Medicine, Atlanta, Ga, succumbed to an illness that he had fought for 4 years with uncommon bravery, strength of character, and infinite grace. Those of us who knew and loved him will miss him greatly; but it is our profession, which is now bereft of one of its strongest leaders, that will suffer without his guidance and moral strength. He was blessed with great intelligence and sparkling wit, but of greater importance was his dedication to truth and candor. This dedication was like a beacon for all of us in surgery. He could never, and did not, abide pomposity, deceit, and cant.

You well might ask about the forces that shaped this consummate academic surgeon. Certainly, first were his parents and siblings. He was raised in a family committed to traditional values—honesty, integrity, and responsibility—and it was these traits that were demonstrated throughout his professional career.

Dean was born in Miami, Fla, in 1924 and, incidentally, in the very hospital to which he returned in 1963 as chief of the surgical services. He grew up in Lakeland, Fla, where he received his precollege education. After a year at the University of Florida, Gainesville, he enlisted in the US Marine Corps in 1943 to fight for his country in World War II. However, his uncommon intelligence was noted, and shortly thereafter he was sent to Dartmouth College, Hanover, NH, by the armed forces. In 1950, he graduated from The Johns Hopkins School of Medicine, Baltimore, Md, where he was elected to Alpha Omega Alpha. His surgical education began there, at The Johns Hopkins Hospital. He then went to the University of Michigan, Ann Arbor, for 1 year before completing the final 3 years of surgical training at the Barnes Hospital in St Louis, Mo, under the redoubtable Carl Moyer. On completion of his residency in 1955, he accepted a position in Harry Muller's department at the University of Virginia, Charlottesville. One year later he was selected as a John and Mary Markle Scholar and began his elegant and seminal studies in portal

hypertension. During these halcyon days of the Markle scholarships, I first came to know Dean Warren. Attracted by his keen wit and incisive powers of logic, I became an admiring acquaintance.

He rose steadily through the academic ranks until 1962, when as an associate professor at the University of Virginia he was offered and accepted the chair of surgery at the University of Miami to begin in 1963. We met at the Southern Surgical Association meeting in December 1962, where I queried his decision as perhaps not demonstrating his usual good sense. His reply indicated a vision of great potential in Miami—further proof of his remarkable diagnostic abilities. I joined him in 1965, and we worked together until he accepted the chair at Emory in 1971. During those 6 years and because of Dean Warren, mine was the best job in academic surgery. He created an aura of excitement and purpose, which molded that fledgling department into a happy and productive academic unit. His climb to national prominence in surgery was well under way during his tenure in Miami, but following his work at Emory in portal hypertension, he became an international leader in this field.

During his life he received many honors, which included the presidencies of the American College of Surgeons, the American Surgical Association, the Southern Surgical Association, and the Society for Surgery of the Alimentary Tract. He served as chairman of the Residency Review Committee and vice-chairman of the American Board of Surgery. He was a member of the Surgery Training Committee and the Surgery B Study Section, both of the National Institutes of Health, Bethesda, Md. Surgical journals sought his expertise, and he functioned on the editorial boards of *Surgery, American Journal of Surgery,* and *Surgery, Gynecology and Obstetrics.* Yet with all these honors, including honorary fellowship in the Royal College of Physicians and Surgeons of Glasgow, one of his most prized possessions was "Chair of Medicine," awarded to him by his colleagues in the Department of Medicine at the University of Virginia on the occasion of his departure to Miami and in recognition of his abilities as the compleat physician.

Dean leaves behind a loving family: his wife, Eileen; son, Dean; and daughters, Patty, Penny, Becky, and Amy. Our hearts go out to them in this time of bereavement. Our loss in surgery on his death is great, but theirs is truly massive. We weep with them but take solace in the knowledge that the world is a better place for his having lived in it.

ROBERT ZEPPA, MD
Miami, Fla

Dr Warren touched the careers of many individuals in our profession. He possessed those rare qualities of leadership that come from knowledge, vision, intellectual honesty, and a penetrating wit. I always knew him as one who was right on the issues and willing to be counted, without being either unreasonable or insensitive to the position and feelings of others. There were times when his knowledge seemed encyclopedic. He was known as the "gentleman surgeon" who was constantly on the clinical and research cutting edge of his discipline. People in various strata of life were quite comfortable with Dr Warren. He had the uncanny ability to retain the friendship and respect of colleagues even after disagreement. As a role model for surgeons, history will be very kind to him. When we talk of replication in academic surgery, Dr Warren will be that role model to whom we can all refer. Here was a man who could walk with kings and not lose the common touch. He will be remembered and quoted for many years and not solely because of his work in the area of portal hypertension. We need more aristocrats of courage and intelligence like Dr Warren to walk the terra firma and influence the young people in our profession.

Ben Eiseman, MD

. . . the Master Surgeon must be a man of mind, a man of thought, a man who knows his province, the human body, as a whole and not only one of its parts.

RUDOLPH MATAS

On January 1, 1989, Ben Eiseman, MD, professor emeritus of the Department of Surgery, University of Colorado Health Science Center, Denver, retired as book reviewer for the ARCHIVES, a position he has held with unique distinction. With vintage Eiseman humor, he suggested that a fellow from Stratford-upon-Avon, England, might be available if I used FMGs! After publishing more than 350 scientific articles and 150 book reviews, does anyone really believe that Ben Eiseman has retired?

The quality of the man is better manifested by the lives he has touched than his publications. Dr Eiseman has been to his young associates what Winston Churchill was to England in World War II, Bjorn Borg is to tennis, and St Thomas Aquinas is to philosophers. Ever the "idea man," he has been willing to explore new ideas and critically analyze established concepts, and in doing so, he has expanded the views of those around him. What a remarkable legacy! His colleagues believe Ben Eiseman has profoundly influenced the careers of at least two generations of surgeons in America and abroad. His name and presence are legendary in such diverse places as Chile, South Africa, England, Kentucky, China, Singapore, and Thailand.

A native of St Louis, Mo, Ben Eiseman received his undergraduate education at Yale University, New Haven, Conn, (BA, 1939) and was awarded an MD degree by Harvard University, Cambridge, Mass, in 1943. Following his internship at the Massachusetts General Hospital, Boston, Dr Eiseman completed a surgical residency at Barnes Hospital, St Louis, in 1950 and immediately joined the staff as instructor in the Department of Surgery and assistant dean at the Washington University School of Medicine, St Louis. From the beginning, Ben Eiseman was an active surgeon, teacher, and investigator.

In 1953, he began his first 8-year tour (1953-1961) at the

University of Colorado Medical School as chief of the surgical service at the Denver Veterans Administration Medical Center. Ben Eiseman was appointed to the Surgery Chair at the University of Kentucky, Lexington, in 1961 and recruited a faculty of American surgery stalwarts such as Frank Spencer, Rene Menguy, Benjamin Rush, Ward Griffen, and Loren Humphrey. In 1967, he returned to the University of Colorado where he remained to become professor emeritus in the summer of 1988. It was there that he served as chief of surgery at the Denver General Hospital (1967 to 1977) and later as chairman of the department of surgery at the Rose Medical Center (1977 to 1988).

Ben Eiseman's experiences have been as intense and protean as any sugeon on the world scene. His early brilliance as a medical student resulted in his election to Alpha Omega Alpha at Harvard. He served in the Medical Corps of the United States Navy and holds the rank of Rear Admiral, MC, USNR (retired). Ben Eiseman is a member of every prestigious organization in surgery and has held positions of leadership in many of them. His appointments and honors comprise a long list, each of which has been a recognition of the confidence his associates have in his scholarly accomplishments. The proudest description of Ben Eiseman is that of being an "idea man." Ever the supreme thought-stimulator, his short handwritten personal memos are classic. The expansive nature of his knowledge borders on being encyclopedic. He collaborated with James Thompson[1] (Galveston, Tex) to write a classic, "The Visiting Professor," in the *New England Journal of Medicine*.

Ben Eiseman has served on the American Board of Surgery, National Institutes of Health (Bethesda, Md) Surgery Study Section (1961 to 1965), and numerous editorial boards and has presented numerous named lectureships. He is the author of many books, served as book reviewer for a number of journals, and was awarded many honorary fellowships—all coupled with his well-known avocation of mountain climbing. Blessed with a charming wife, Mary, Ben Eiseman is a legend in his own time. The ARCHIVES is grateful for his many years of service and salutes him in what we know will be an "active" retirement.

The Surgeon and Biliary Lithotripsy

Surgeons have been receiving the news of lithotripsy for gallstones with anxiety and some disdain. The initial pieces of the story have seemed to be a rewrite of the advent of endoscopy, biliary stenting for pancreatic cancer, endoscopic polypectomy, and percutaneous drainage of abdominal abscesses. The possibility that an operation done by surgeons since 1882 may be replaced by a procedure not involving an incision, and that this procedure may not be done by surgeons, is disconcerting, to say the least.

While some surgeons have reacted by predicting that lithotripsy will cause gallbladder perforations, obstructed common ducts, and recurrent stones, a reaction that might be interpreted as a sophisticated form of denial, others have preferred to watch and wait, suffering silently, and a few have planned joint ventures, limited partnerships, and other schemes to invest in machines, for motives seemingly transparent, but truly known only to themselves. Hospital administrators, presumably on the advice or even insistence of their medical staffs, have made commitments to purchase machines in response to sales pitches, not scientific data. Mobile units are being developed and tested. Once thought by the federally mandated Health System Agency to be the instruments of cost reduction through sharing, they now are seen as the vehicle for market expansion and perhaps domination. The nearly frantic efforts to market them conjure up visions of an interstate highway traffic jam caused by 20-wheeler gallstone lithotriptors summoned by an all-points call to smash a 7-mm gallstone.

The facts about biliary lithotripsy are far less dramatic and threatening than the rumors and perceptions. German investigators have described the results in 175 highly selected patients.[1] Criteria for entry included reasonably healthy patients who had biliary tract symptoms and one to three noncalcified gallstones with an aggregate diameter of 3.0 cm or less. Visualization of the gallbladder on oral cholecystography was required, and cysts, aneurysms, or lung could not be in the shock wave path. Pregnancy and the presence of a pacemaker were also exclusion criteria. All patients received oral chenodeoxycholic acid and ursodeoxycholic acid prior to lithotripsy and for 3 months following the complete disappearance of stones. The entry and exclusion criteria were met by 28% of those referred to them for lithotripsy. There were no deaths, and the incidence of serious complications, including pancreatitis (1.1%) and the need for endoscopic sphincterotomy (0.6%) or cholecystectomy (0.6%), was acceptable. About 35% of patients had biliary colic days, weeks, or months after the procedure, probably associated with passage of fragments through the duct system. Re-treatment was necessary in 5.1% of the patients because of fragments within the gallbladder that were too large to pass through the cystic duct. The fragments pass out of the gallbladder over time; the overall stone-free rate was 63% within 4 to 8 months, 78% within 8 to 12 months, 91% within 12 to 18 months, and 93% within 18 to 24 months. Follow-up is too short to predict recurrence rate, but after oral dissolution it approximates 40% at 5 years.

At least nine manufacturers have produced gallstone lithotriptors or are developing them. In the United States, gallstone lithotriptors cannot be sold for general use unless they are approved by the Food and Drug Administration after review of data collected in clinical trials to determine safety and efficacy, of which two are currently in process. One of them will also determine the usefulness of ursodeoxycholic acid as adjuvant therapy. The results of these trials are likely to be presented within a few months. In general, one might expect them to be similar to the Munich experience already reported.[1]

Although scientific data from the United States are not yet available, the general impressions of those involved in the clinical trials are fairly uniform: the procedure is not painless, but the discomfort can be easily controlled by analgesics, without anesthesia. Patients can return to normal activity within hours, hospitalization is not necessary, and patient acceptance is very high. Episodes of biliary colic after lithotripsy are tolerated quite well by most patients. The operator must be able to operate an ultrasound device and understand the principles involved. Finally, limitations in the presently available technology will restrict the applicability of lithotripsy to only a segment of symptomatic patients with gallstones.

A lithotriptor may be purchased and used for specified indications if and when the Food and Drug Administration approves the device. Manufacturers will market the machines to radiologists, gastroenterologists, and surgeons. The devices differ to the extent that training must be machine-specific, although the general principles of lithotripsy are applicable to all of them. Training guidelines useful in the credentialing process are already being developed by a group of radiologists, gastroenterologists, urologists, and surgeons who represent organizations within their disciplines. Those already involved have recognized that an interdisciplinary approach will be necessary to provide the best possible care for the patient. The diagnostic expertise of the gastroenterologist as well as the imaging and ultrasound skills of the radiologist are invaluable. The procedural and technical skills of the surgeon as well as his or her availability, experience, and facilities for outpatient follow-up after procedures are necessary for the highest quality of care.

Surgeons must be involved from the beginning, even though the technology is imperfect and the number of patients eligible for lithotripsy at first will be small. At present, we should keep ourselves and our hospital administrators abreast of the results of the clinical trials, carefully evaluating all available data. Groups of surgeons will need to work with their hospital administrators to collect the information necessary to make an informed decision about the advisability of purchasing a device if the procedure is found to be safe and effective. Surgeons should also take the lead in organizing the interdisciplinary team and in developing its modus operandi.

The usefulness of biliary lithotripsy and the breadth of its applicability will be under study for many years. Technologic advances undoubtedly will result in several generations of devices. Surgeons have always acknowledged that superior surgical care before and after an operation is as important to a successful outcome and a happy patient as the operation itself. As distasteful as it may be to some, we must now acknowledge that the procedures from which our patients may benefit in the future may not always involve an incision, sponges, scissors, or sutures. We owe it to our patients to be ready with biliary lithotripsy if and when it proves to be best for our patients. If we are not properly prepared to serve them, others shall do so without us, and we shall have deserved our fate.

David L. Nahrwold, MD
Chicago, Ill

Western Surgical Association

In this issue of the *Archives of Surgery*, we are pleased to present the scientific transactions of the 96th Annual Program of the Western Surgical Association (WSA) held in San Diego, Calif. Founded in 1891, the Association elected S. S. Todd of Topeka, Kan, as its first president. The original name of the organization was the Western Association of Obstetricians and Gynecologists, which was changed to the Western Surgical and Gynecological Association in 1892 and to the Western Surgical Association in 1909.

The WSA presidency has been held by such American surgical stalwarts as Drs Warren H. Cole, James T. Priestley, Charles Mayo (two generations, 1904 and 1963), O. Theron Clagett, Thomas Orr, and Chester B. McVay, and in more recent years by Drs George L. Jordan, Martin A. Adson, R. Dale Liechty, Alexander J. Walt, Melvin A. Block, and J. Bradley Aust, the current president. Dr Willis Gatek served in this position for 3 years during World War II (1942 to 1944).

The WSA meetings have convened in such widespread geographic areas as Chicago, Ill, and Detroit, Mich, in the east, Seattle, Wash, and San Diego, Calif, in the west, as far north as Minneapolis, Minn, and Rochester, Minn, and as far south as Galveston, Tex. Senior members will long remember the 1924 WSA meeting in French Lick Springs, Ind. There exists within the association's 200 plus members a strong sense of professionalism, camaraderie, and pride.

The presidents of the WSA have had a high profile in American surgery. Three have been elected to the presidency of the American Surgical Association. Three were chairmen of the American Board of Surgery; 7 served as vice-chairmen; and 16 served as directors of the Board. Six were elected to the presidency of the American College of Surgeons; 3 served as chairmen of the board of regents; and 16 served as regents of the College. Three previous WSA presidents have been chairmen of the Residency Review Committee for Surgery, and 16 served as members of the Residency Review Committee, including the current president. Thirty-three former presidents were department chairmen; 3 served as editors of refereed surgery journals, 3 as editors of major textbooks of surgery, and 5 served on the National Institutes of Health Surgery Study Section. The *Archives of Surgery* looks forward to a continued relationship with the WSA.

They Call It Competition

Presidential Address

Melvin A. Block, MD, PhD

It is not often that one has the opportunity to discuss a subject, personally selected, before a more or less captive audience with the sophistication of the membership of the Western Surgical Association. It is a distinct honor. In selecting this subject, I took the advice of Dr Dale Liechty, a former president of the Association, to editorialize. In selecting this title, I recalled a historical novel read many years ago, *They Call It Patriotism*, in which intrigue involved in the initiation of World War I was emphasized.[1] Although intrigue is not, I believe, dominant in the changing role of competition in medicine and surgery, there are ramifications that permit a commentary. Samuel Johnson is said to have opined to the effect that patriotism in public life is the last refuge of the scoundrel. Manipulation of competition may be considered the last refuge of the scoundrel in medicine and surgery.

I hope that this introduction does not lead to the thought, "Oh, not another talk on the business of surgery." The essence of my thoughts is a desire to emphasize the following: (1) there is much in medicine and surgery that makes competition different from other major endeavors in life; (2) that "tools" are critical for advances in surgery and can be considered not only tools for surgical diagnosis and treatment, but instruments of competition; (3) that competition is inherent in all of life and should be incorporated into actions that lead to the best medical outcomes for patients and physicians; and (4) that the impact of competition in medicine and surgery appears to be increasing.

Obviously, this subject is broad and complex. I have no intention or capability of discussing it in depth, bringing new ideas or proposals, or providing precise new data or statistical information. I will provide only a commentary, only observations. This will be slanted toward surgery and the Western Surgical Association.

BROAD CHARACTERISTICS OF COMPETITION IN MEDICINE

The spectrum of competition in medicine is expansive, extending from interactions among individual physicians to broad societal policy determinations. There will be competition in life's endeavors whenever there are at least two individuals present. Physicians are attainers. It may appear that most of the competition in medicine, broadly speaking, currently relates to marketing efforts, costs, and consolidation. These elements cannot be ignored, but they do not represent all that is important for competition in medicine. Competition in medicine and surgery does involve many factors, including the following, which are not listed in any particular order:

1. The attraction of patients through personal and organizational marketing efforts.
2. Innovative medical care techniques, especially in specialties.
3. Personalized, individual medical care.
4. Public service responsibilities. This raises the question, is medicine a public utility? Also involved are issues of preventive medicine, public health, and sanitation. A sense of responsibility by physicians and patients is necessary.
5. Regulatory controls, including licensure, public and professional credentialing, antitrust legislation, and reimbursement.
6. Economic factors are basic. Included are price competition, patient demand, costs of regulation, incentives, and profit vs nonprofit motivation.
7. Supply of physicians, including specialists and other health care personnel.
8. Dissemination of information, technical and otherwise, in meeting and creating demand.
9. Quality and outcome of medical care.
10. Tradition.

From a historical standpoint, medical care has always incorporated the desire of people for personal care during illness as well as protection from disease. However, it is generally recognized that advances in public health have been responsible, much more than clinical medicine, for improvements in life expectancy, overall health levels, and quality of life. Focusing on personal aspects of medical care, a level of trust is usually necessary between the patient and physician. This involves costs, in terms of time and personal interaction, over and above the basic diagnosis and treatment. Competition in medicine involves much more than supply and demand.

Underlying any subject dealing with medicine as a service activity is the difficult-to-define entity termed "quality of care."

Accepted for publication February 3, 1989.

From the Department of Surgery, Scripps Clinic Medical Group, La Jolla, Calif.

Presented as the presidential address at the 96th Annual Meeting of the Western Surgical Association, San Diego, Calif, November 14, 1989.

CERTAIN UNIQUE CHARACTERISTICS OF COMPETITION IN MEDICINE

There are features of competition in medicine and surgery over and above public service aspects that distinguish these professional activities from pure business activities. These activities are discussed below.

Free Sharing of Knowledge and Experience

Historically, sharing experiences, new treatment techniques, and results of treatment has been an accepted way of life among physicians. This does not include the business functions that develop and provide medications and the physical wherewithall of medicine and surgery. In general, medical and surgical treatment modalities have not been patented. Of course, economic factors have led to patents for certain tools or mechanical devices in medicine and surgery. However, for the most part, secrets have not been a part of treatment modalities. The profit motive has not been a dominant factor in the service or direct patient component of medicine, although it has been in the more purely business sector. Competition becomes more obvious whenever profit motives dominate.

Meetings of societies, such as the Western Surgical Association, continuing medical education courses, publication of papers and books, travel to medical centers, and discussions with physicians have been a part of this free exchange of information and experience. These efforts also serve to control the quality of care; any treatment proposed must stand the tests of use by others and time. Medicine and surgery are not exact sciences and cannot be evaluated on the basis of an expectation of perfection. However, biologic laws are not easily manipulated and erroneous or dishonest reports do not stand the test of time. Limitations inherent in medicine are evidenced by the fact that no one, to our knowledge, has lived forever. Under these circumstances, the free exchange of information is essential.

We must wonder that if competition continues in the direction now apparent, will free exchange of information and experience in medicine continue? There have been governmental stimuli for competition in the form of selective deregulation, relative especially to costs, but also in advertising and possibly in credentialing. Will the populace truly be better served by this selective deregulation?

The presentation and publication of professional reports after peer review is perhaps the best form of advertising. Those characteristics that are unique and that distinguish the medical profession from most other endeavors do not appear to be appreciated by much of the public. Thus, meetings of the Western Surgical Association differ markedly from the casual meetings of mercantilists described by Adam Smith as conspiracies to restrain trade.

Will vicious competition eventually destroy the traditional free interchange of information in surgery and the importance of meetings such as those of our Association? It seems unlikely, but preservation may require effort.

Operational Policies in Hospitals

Hospitals, the workplace of surgeons, have undergone major operational changes in recent decades. Hospital working environments obviously have a major influence on surgeons. In the past, a large percentage of hospitals have been projects of religious organizations and incorporated basic religious tenets, including requesting that physicians on the medical staff donate a certain amount of free patient care. Of importance was the nonprofit status of these hospitals. In the distant past, it was economically difficult for a private enterprise hospital to exist. However, with the advent of certain changes in tax laws and reimbursement systems, as well as an emphasis on managerial expertise, for-profit hospitals and medical institutions have developed. As part of this movement, competition through marketing activities, recruitment of physicians by hospitals, acquisition of competitive technological equipment, and consolidation under reimbursement plans have appeared.

Changes in hospital activities in recent years have led to questions of whether hospitals now better meet their responsibilities. Hospitals have been subject to tremendous pressures. Overall, national and international economic instability has had an impact on costs, particularly because hospitals are labor intensive and technology intensive and are subject to increasing governmental controls. Governmental policies in the 1950s and, in particular, the Hill-Burton legislation stimulated the growth of hospitals, many of them small community hospitals. In recent years, the pressures of increased and unstable costs and changing reimbursement policies have not only emphasized competition among hospitals, but have had a great impact on their public service role and, for a large number of them, their actual survival. Under such circumstances, it is conceivable that the patient entering the medical facility is viewed as the raw product and the dollar, not the satisfied and properly cared for patient as the end product. Physicians, as primary actors in the hospital environment, are caught up in these monumental changes in hospitals.

A major and unique responsibility of hospitals and physician staffs has been to control the quality of patient care. In general, hospitals have been required to monitor medical and surgical care to meet generally accepted standards, primarily those of nongovernmental bodies. However, increasingly, governmental agencies are injecting stronger influence in the operation of hospitals. Conflicts and confusion arise when different governmental agencies place conflicting requirements before hospitals and their medical staffs. The expense of regulation must include the costs of related loss of productivity. The unique characteristics of quasipublic hospitals and medical staffs in providing realistic quality assurance within an atmosphere of growing competition, governmental impact, medicolegal liability, and economic constraints require recognition, honesty, pragmatism, and integrity by all concerned.

There can be no doubt that hospitals must be operated like a business. But we must question whether the competitive aspects of the hospital business have gone too far. It may be time to redefine the role of hospitals, emphasize the expenditure of resources on patient care, assure support where needed, and develop national economic policies that permit greater stability in financial operations. Surgeons have an inherent interest in the optimal functioning of hospitals.

Surgeons are obliged to provide active, honest support to hospitals, above competitive issues such as allocation of operating room space and time. It is in credentialing, utilization review, and quality assurance that the best and not the worst features of competition are needed. If the profession cannot handle this, nonprofessional bodies take over with expected problems.

Patient Referral Patterns

Patients' freedom to choose their physicians has been a basic principle in medical care in the treatment of illness. This has meant that individuals depend on word of mouth or the advice of physicians in selecting personal physicians. Neither of these avenues may be based, to a great degree, on professional competence. Some patient referrals have been on the basis of relationships among physicians, including referrals within physician groups.

Obviously, competitive factors can enter into patient referrals. In particular, economic factors can play a prominent role. The desire for personal gain, part of human nature, can be

Melvin A. Block, MD, PhD

substantial. Thus, surgery has had to battle fee splitting in its various forms. Physicians must provide satisfactory results and personal interaction or the referring physician can suffer in the opinion of the patient.

However, patients have much difficulty in assessing desired results. The segregation of patients into groups with physician and hospital alignments on the basis of reimbursement (eg, health maintenance organizations, preferred provider organizations, independent physician associations, and medical plans of insurance companies) obviously has had a great impact on patient referral. Specialty physicians, however, are sufficiently numerous in some of these medical groups that competitive factors within specialties occur. The gatekeeper policy, by which designated physicians control referral, can impinge on patients having access to specialty physicians, including surgeons, as a result of economic factors.

From a pragmatic viewpoint, the segregation of patients on the basis of reimbursement may help to reduce and rationalize pure economic factors among physicians as a major factor in the referral of patients. However, the question of personal selection of, and access to, specialty physicians should continue to be a matter for the individual citizen to decide, although personal resources will be a necessary factor. We must now ask if, in the setting of utilization review in hospitals and ambulatory care facilities, experience makes second opinions and preadmission review only an additional cost? It is critical that surgeons play a role in utilization review in its various applications.

Advertising

Advertising is a major component of marketing. Until recently, advertising to the public has been discouraged by many medical organizations. It has been considered unprofessional and prone to overt or hidden incompleteness, misrepresentation, or dishonesty. Governmental actions have removed the effective implementation of any policies by medical societies to significantly influence advertising. Advertising can provide significant information and, as such, is competitively advantageous. But it can be easily modified to make claims and comparisons that may or may not be factual so as to permit the inexperienced to make rational decisions. Advertising is a prime example of that which is seen can be beautiful, but that which is not seen is essential. Evidence indicates that it pays to advertise. Witness the sheep grazing and bearing a sign, "Eat more beef." Truth in advertising is critical in medicine. Who should assure this?

There appears to be an increased desire by the public for medical information. Therefore, the dissemination of appropriate and concise but complete and accurate medical data is important. Can competition assure this in a timely fashion? Can the government accomplish this? Without sufficient experience, people have difficulty evaluating medical information. Many depend on conclusions from sources considered reliable but not necessarily so. Others are easily influenced by the fanfare associated with advertising. "Buyer beware" is likely to be increasing and, once again, critical for the patient to assess medical advertising and care in our new world of competition.

Advertising also encompasses the free exchange of information among physicians. There can be no better modality for the dissemination of experience, expertise, or interests than the presentation and publication of professional reports that have undergone peer review. The Western Surgical Association provides such opportunities. There are similar opportunities throughout medicine. Again, fierce competition must not engender fraudulent publication. Medical publications also permit the needed dissemination of information among subspecialties.

Advertising and marketing also relate to the credentialing of physicians for medical care. Competitive factors have brought this matter increasingly into focus. How should information about expertise and credentialing be distributed to permit the public and physicians to make medical care decisions? What criteria are to be used to determine which information is to be made available? It must be hoped that our profession can prevent manipulation in these matters.

Credentialing

Physicians have long had the freedom and the responsibility to monitor the clinical activities of their colleagues. Standards of training, experience, and demonstrated levels of performance, even though not precise and always changing, have been a mainstay in this endeavor. Competition has also played an important role. It is good when promoting optimal standards and bad when greed intervenes.

Increasing constraints now affect credentialing with the government, reflecting public attitudes and giving conflicting directions about who is to provide medical care and policies for monitoring competence, sometimes as a result of influence by competing groups. Medical associations find aggressive development and enforcement by the government of antitrust policies and deregulation of providers of medical care confusing relative to governmental, state, and federal edicts and expectations of self-policing. In this, help, and not an adversarial position, is needed from the legal profession.

The Role of Money

Money, or what money represents, has and always will play a dominant role in human interaction, in competition. However, there are unique features about the place of money in medicine, both in compensation to physicians and other medical personnel and in funding for medical care and research in the public interest. Dr Alexander Walt has commented that

the costs of attempting to provide an indefinitely long life are infinite.

I have been told by successful businesspeople that the desire for money is essential to success in the pure business world. From a business standpoint, products are priced as commodities; what the market will bear. However, there has been an idealistic undertone in medicine that postulates that money should not play a dominant or primary role in the profession. In this I fall back to precepts learned where I received my medical education and where I have spent most of my life; that physicians should have a comfortable life, and that they perform best when patient care, and not money, is the dominant incentive and competitive factor.

Too often, the desire for money becomes entangled with greed; it is likely to be more so in the business world. Yet, even in business, the company that survives and succeeds is the one that provides quality for a needed item. Although there must be financial responsibility in medical care, if attainment of money becomes the overwhelming objective, greed is not far behind, and all ultimately suffer. Ego and money can also become intertwined.

Medicine has been unique in its attempt to prevent the domination of money and greed. Most physicians possess an inherent integrity and educational background that place honesty and patient welfare above greed. But aberrations occur, and the incentives placed before physicians can alter balances. Patients are well advised to know the incentives under which their physicians work; incentives do modify competition and judgment. It is possible for judgment and skill to also be altered when a surgeon is either too busy or not sufficiently busy.

Obviously, productivity must, in a realistic fashion, always match compensation. Aberrations will occur because of a number of factors, such as supply and demand, incentive arrangements, unusual circumstances, actions by regulatory bodies, and competitive forces. It is likely that reimbursement patterns for patient care will increasingly place greater controls on physician incomes. The economic disorders of the world during the last several decades have greatly increased the importance of money in all areas of life.

Personal service dominates medical care and, therefore, physicians will always maintain primary control. Nevertheless, because physicians are a component of third-party determinations of patient populations and reimbursement, competitive factors inherent in such business and governmental influences can affect this personal care regardless of the setting. The physician's attention is increasingly directed away from patient care to financial factors, such as acquisition of patients, time expenditures, use of tests, and conflicts between quality care and reimbursement. The concept that if excellent patient care is provided, financial matters will take care of themselves is no longer likely to be true for physicians.

Competition for the resources of government and business for medical research is overwhelming. Money alone does not guarantee success. Leaders who are capable of responsible and effective allocation of limited financial support are rare.

The Right to Unlimited Medical Care vs Controls on Distribution of Medical Care

Unique competitive factors immediately arise if medical care is limited by funds but not those precisely of patients in a background of political vote capturing, a populace with unlimited expectations, incentives stimulating services by physicians, and an increasing availability of costly technology, some of which is unproved and may be subject to overuse. Maneuvers designed to increase competition among physicians and thereby reduce costs have not been successful. The government and certain prospective payment plans have attempted, in essence, to place the onus of reducing utilization and medical care costs on the physician. A cynical explanation might be that physicians as a group have little voting power and the politics of government do not permit actions that tarnish government as the great benefactor. A penetrating analysis leads to the conclusion that there are fundamental errors in expecting physicians alone to make these corrections in utilization and costs of medical care.

A host of factors and complexities, some peculiar to medicine, have contributed to inflated costs in recent years, but emphasis must be placed on an increasing overall utilization (demand inflation) of medical care by people expecting full and immediate access to the constantly advancing technology (cost inflation), with either perfect results or high medicolegal compensation. Until individuals have a significant responsibility for determining medical care on the basis of affordability, and until medical malpractice can be separated from a system of compensation for unfavorable results, it seems unlikely that a "balanced budget" for overall medical care will occur.

The separation of medical care into that which is mandatory and that which is primarily elective undoubtedly is involved in much of the sorting out of third-party reimbursement. As of now, people don't seem to want to face these directions. Although a reduction and readjustment of physician income is likely, it seems highly unlikely that this will ever, in itself, provide a significant resolution—just as price controls and wage freezes fail to control inflation for very long. Nevertheless, physicians are best able to determine what medical care is unneeded and ineffective. A workable resolution between public expectations and affordability of medical care in this country requires input by physicians and the people.

THE IMPACT OF TOOLS IN COMPETITION

Research and development are recognized requirements for business to maintain viability and a competitive stance. These tools, such as instruments and techniques, are critical in research as well as in production and service. The confluence of improved techniques and new tools, along with increased basic knowledge, leads to significant advances. Competition in medicine requires physicians to improve their skills and to use new and proved techniques.

Gimmicks develop in all areas of life and misleading promotion can be a form of manipulation. Each development must be tested for its value and risks. Nevertheless, there is hardly anything we do in medicine and surgery that cannot be done better. Virtually every operative procedure I now perform is distinctly different from that which I was taught in my residency. The physician must "keep up," not only to remain competitive, but in the best interest of patients.

To compete requires information. Information can be considered a tool of competition. The current time period can be considered a communications revolution. However, more information may be provided than can be digested. Easily missing are an evaluation and determination of the quality of information. "Junk" information abounds. Medicine and surgery are unique in providing peer review of information through organizations such as ours.

By way of illustration, I would like to relate some personal experiences that emphasize the importance of using clinical material available to us, the free interchange of information, and the tools in diagnosis and treatment. It has been a privilege to be associated with institutions that stimulate efforts to achieve advances in clinical medicine and surgery. Crucial for such achievements are having a large number of patients to register problems and the development of tools and techniques to provide answers to these questions. Medicine and surgery are inexact sciences, and we learn from our patients.

This is a privilege. It is the confluence of observations, usually from a number of inquisitive individuals, that permits and stimulates progress. This can be illustrated by recognizing the clinical characteristics of an unusual entity, medullary thyroid carcinoma.

Some years ago, our interest was stimulated by a patient who presented with a thyroid nodule. She indicated that five sisters had been treated for thyroid carcinoma.[2] This patient and subsequent patients permitted many of us at the Henry Ford Hospital, Detroit, Mich, to participate in the evolving understanding of medullary thyroid carcinoma and its relationship to certain other endocrine neoplasms and malignancy in general. Only a few years earlier, in 1965, the hereditary occurrence of medullary thyroid carcinoma had been observed and reported.[3] It was at this time that multiple endocrine neoplasia syndromes, then unnamed as such, were being recognized.[3] Also at this time (1966), Williams[4] astutely correlated pathologic features of medullary thyroid carcinoma, described only a few years before (1951, 1959), and recognized the origin of the thyroid from parafollicular cells.[5,6]

In 1964, Foster et al[7] reported that these parafollicular cells produce calcitonin, a substance identified by independent researchers in 1961 and 1962, with an origin from the thyroid gland recorded in 1963.[8,9] Excess production of calcitonin by medullary thyroid carcinoma was identified in 1968, and in 1970 a dependable immunoassay for calcitonin was recorded.[10,11] Thus, the convergence of clinical observations of a distinct thyroid carcinoma arising from the parafollicular or C cells of the thyroid gland; the recognition of a familial occurrence and an association of this malignancy with other endocrine lesions; the discovery of the humoral agent, calcitonin, with its physiologic properties; the recognition of the production of calcitonin by C cells and by medullary thyroid carcinoma; and the development of a clinically applicable technique for the assay of serum calcitonin permitted understanding and reasonably effective diagnosis and treatment for medullary thyroid carcinoma. Many individuals contributed to this research and freely shared their discoveries to make this rapid sequence of events possible.

In subsequent years, the tools for studying patients with the multiple endocrine neoplasia syndrome, type II, have provided a model to document certain important basic characteristics of malignancy, as discussed below.

Invasive Malignancy Characteristically Is Preceded by a State of Noninvasive Cellular Alterations, Including Morphologically Identifiable Cellular Hyperplasia

Morphologic characteristics of cells reflect a progression of intrinsic molecular changes within cells, ultimately leading to life-endangering malignancy. For medullary thyroid carcinoma, C-cell hyperplasia is a preceding event.[12] This has tremendous positive implications, already recognized for other carcinomas, such as those of the uterine cervix and breast, in offering a "window" to permit diagnosis and treatment when it can be curative. In the case of the unusual entity, hereditary medullary thyroid carcinoma, recognition of C-cell hyperplasia, and/or preclinical invasive carcinoma is relatively easy because family members can be screened for a marker—an elevated level of serum calcitonin after provocative testing with pentagastrin, with or without calcium.[13] Indicators for the presence of preclinical malignancy or the progenitor of malignancy are desperately needed for all malignancies.

The Evolution of Malignancy, at the Preinvasive State, Appears to Involve at Least Several Fundamental Molecular Alterations Within Cells

This is implied in medullary thyroid carcinoma by observations such as the recognition of patients having the sporadic variety at an older average age than those with the hereditary type.[14] Presumably, the hereditary medullary thyroid carcinoma has a preexisting genetic abnormality or instability that awaits a second major alteration to engineer malignancy that is recognizable to us currently at the stage of morphologic cellular abnormalities and gross tumor formation.

Evidence places the genetic marker for multiple endocrine neoplasia, type IIA, on chromosome 10 by linkage.[15,16] Detailed mapping of DNA markers should permit more precise screening of family members at risk for medullary thyroid carcinoma, and, we hope, a better understanding of the disease, as well as gene structure and function.[17] Predicting the risk for hereditary medullary thyroid carcinoma for the individual as well as offspring on the basis of gene testing is not a simple matter, however, as has been evident in the case of hereditary retinoblastoma.[18] Other studies now relate the locus of gene abnormalities to other hereditary neoplasia, including colon and breast carcinoma.[19] Thus, hereditary medullary thyroid carcinoma and similar entities provide a fantastic tool to use in our attempts to better understand the basis of malignancy and, thereafter, for prevention and more effective treatment.

Correlation Between Size of Those Malignancies That Tend to Metastasize and the Likelihood of Metastasis

For preclinical (microscopically) hereditary medullary thyroid carcinoma or C-cell hyperplasia identified by screening studies that demonstrate an elevation of serum calcitonin level, total thyroidectomy is curative in nearly all cases.[2] This is documented by a return to normal levels of serum calcitonin, even after provocation, over long periods, thus indicating absence of metastatic disease. However, when medullary thyroid carcinoma is of sufficient size to be palpable, virtually all have metastases, even though they are microscopic. Elevated levels of serum calcitonin serve to denote the presence of these occult metastases.

Metastases of Carcinoma Can Be Dormant and Unimportant Clinically for Many Years or Even a Lifetime

Medullary thyroid carcinoma can be eradicated from the neck, but subclinical distant metastases can be evident by a persistent elevation of serum calcitonin.[20] The level of serum calcitonin does relate to the extent of metastases and the likelihood of clinical manifestations. Unpredictably, such metastases may remain dormant, however, and never produce great increases in serum calcitonin levels, thus indicating a state of coexistence within the body—or they may at any time progress in size and clinical significance to ultimately kill. It is in this setting that the immunologic factors may have their greatest influence on malignancy.

There Appear to Be Significant Differences Between Malignancy That Is Hereditary Compared With That of a Sporadic Nature

The hereditary variety of medullary thyroid carcinoma is always bilateral, whereas the sporadic type is unilateral in origin.[21] Furthermore, C-cell hyperplasia outside the focus of carcinoma or concentration of C-cell hyperplasia is present diffusely throughout the entire thyroid gland. This extent of C-cell hyperplasia in the thyroid gland outside the tumor is not, in general, evident in the sporadic variety of medullary thyroid carcinoma. Also, hereditary medullary thyroid carcinoma is often associated with other endocrine neoplasms (the multiple endocrine neoplasia type II syndrome), whereas sporadic medullary thyroid carcinoma is not.

Although important clinical manifestations of genetic and

sporadic medullary thyroid carcinoma may not be greatly different, basic characteristics of these two variations of the same malignancy alter these effects, such as age of patient at appearance and extent of operation needed. Thus, for hereditary medullary thyroid carcinoma, a total thyroidectomy is imperative, whereas this is not as necessary for most cases of the sporadic type. A host of factors, such as "initiators" and "promotors" of malignancy, evidently can modify manifestations of malignancy, and this carries over to our clinical practices.

We, as clinicians, must hope that those expending their lives in basic research ultimately provide the tools to answer questions about the origin and treatment of disease. The road is long and arduous. The ringing telephone can keep clinicians from effective clinical research, but probing the unknown by those in basic research can be frustrating and time-consuming. Even here there is competition; competition is everywhere. We may even compete with ourselves. Dr Frank Mann, a pioneer in surgical research at the Mayo Clinic, Rochester, Minn, emphasized that a single significant discovery during a lifetime of research means success.

PERSPECTIVES

Competition is a fundamental and inherent aspect of human interaction. Basic to medicine is patient welfare. Vagaries exist in definitions of basic care, quality of care, justified costs, payment methodology, performance, and physician certification for services. From a pragmatic standpoint, we should expect increasing movements outside the medical profession to influence all of medicine and surgery. It is likely that medicine will need to honestly insist on actions that preserve patient welfare within an atmosphere of many competitive factors.

Economic pressures facing businesses no longer able to cope with increasing costs, particularly if the acquired immunodeficiency syndrome increases liabilities substantially, similar reactions by private insurers, and the political realities of an aging population and Medicare system may further push a government-dominated health system. We must hope that physicians do not increasingly become governmental employees with all of the inherent negative aspects of reduced competitive factors. It appears that a spectrum of health care plans will further segregate patients, physicians, and hospitals. These plans and groups may represent the competitive forces involved in providing medical care. Physicians, though less competitive individually, retain responsibility for patient welfare. This alone will require activities of a competitive nature.

For some patients, desire and financial capability will always make highly personalized, private care with additional physician time a reality. The varied roles of government will likely influence the extent of private care greatly. High-quality medical care in the technical context is not necessarily expensive, but the expenditure of physician time in conversations and paperwork can be expensive. As a result of governmental economic dislocations over recent decades, is limited medical care a part of the reduced standard-of-living forecast for this country? The many faces of competition may increasingly be declared in a variety of forms of litigation, including litigation among physicians and the application of antitrust laws. Regulatory conflicts related to either mandatory or outlawed uniform fees or reimbursement (depending on the organization involved) on the basis of antitrust or competition issues can place physicians in a catch-22 position. In these situations, price competition takes ironic twists.

Performance by physicians may be the ultimate measure of competition; the same applies to any occupation. But how is performance defined and measured? This must involve technical as well as patient satisfaction factors leading to generally expected outcomes. Constant attention to valid improvements, avoidance of overconfidence, efforts to keep up, and a continuing recognition of patient needs and desires are positions likely to produce a high level of performance. Competitive stimuli can also be helpful. External economic factors, however, can significantly modify physician performance.

From the perspective of tools and technology, surgery is changing immensely. The trend has been from large to smaller operations, and to endoscopic procedures and microsurgery. Invasive medical subspecialties have and will continue to remove more procedures from the province of surgeons. Trauma, transplantation, and modified procedures for malignancy increasingly dominate general surgery activities. There are now departments of minimally invasive surgery. To remain competitive, surgeons must constantly sort out the good from the morass of technology and keep an open mind for that which represents a definite advance.

A look at the past makes one optimistic. Rarely do dire predictions fully unfold. It is the optimism, energy, and enthusiasm of youth that eventually lead to positive developments. As Dr William Mayo once said, "Each day as I go through the hospital surrounded by younger men, they give me of their dreams and I give them of my experience, and I get the better of the exchange." But, for medicine, the coming years may also affirm Samuel Johnson's description of a second marriage: a test of hope against experience.

May our educational systems enable physicians to understand the unique and positive attributes of competition, but also the need to avoid the ever-lingering potential negatives. Competition, it is hoped, prevents stagnation and "stonewalling" of efforts for improvement. It also promotes the efficient allocation of resources, yet is not governed by greed, incompetence, and dishonesty.

For the Western Surgical Association, renewal comes from new members. Should the Association be contemplating changes now, realizing the movements that are occurring in medicine and surgery? Change for the sake of change is unwarranted and usually unproductive. The maintenance of established objectives, with an appreciation for the role of competition in the life of surgeons, appears to be the road to follow. We need the viewpoints of new members to provide direction for the Association.

Much of the idealism in medicine and surgery should be preserved. To accommodate and incorporate, within the framework of surgery, that which provides the best for patients and physicians alike can be agreed on generally, although significant details may never be acceptable to every individual involved. Dislocations will likely increase before stability occurs in medical care. A great sorting out of systems for health care, reimbursement, incentives for patients and physicians, and competition is evolving.

Increasingly, we are all entries in data banks. Those to be involved in regulation must realize that there are critical differences in medical care within the concepts of competition and much that is unique in medicine should be retained. Efforts to correct inappropriate conduct by a few physicians should not lead to crushing regulation that is stifling and costly. It is not possible to legislate good medical care; nor does increased competition or deregulation do it. The differences in orientation between business and medicine and government (the people) and medicine are likely to require continuing negotiation with formats currently under development. Physicians should provide leadership for the retention of social responsibility, within and without the profession, and the setting of ever-changing limits in medical care. It must be hoped that improvements do not await our country, including our profession, attracting "a better class of people."

A Randomized Trial of Less Intense Postoperative Warfarin or Aspirin Therapy in the Prevention of Venous Thromboembolism After Surgery for Fractured Hip

Peter J. Powers, MD; Michael Gent, MSc; Richard M. Jay, MD; Denise H. Julian, MSc; A. G. G. Turpie, MB; Mark Levine, MD, MSc; Jack Hirsh, MD

A randomized trial was carried out with 194 patients to compare the effectiveness of sodium warfarin or aspirin with that of placebo in the prevention of venous thromboembolism after surgery for fractured hip. Prophylaxis was commenced postoperatively and continued for 21 days or until patient discharge, whichever was earlier. All patients underwent surveillance with iodine 125-fibrinogen leg scanning and impedance plethysmography, with subsequent venography. Venous thromboembolism occurred in 13 patients (20.0%) in the warfarin group, 27 patients (40.9%) in the aspirin group, and 29 patients (46.0%) in the placebo group. Proximal vein thrombosis or pulmonary embolism occurred in 6 patients (9.2%) in the warfarin group, 7 patients (10.6%) in the aspirin group, and 19 patients (30.2%) in the placebo group. The results of this study show that sodium warfarin therapy is safe and effective in preventing thromboembolic complications in patients undergoing surgery for fractured hip, and that aspirin therapy is an equally safe and effective method for preventing proximal vein thrombosis or pulmonary embolism (*Arch Intern Med*. 1989;149:771-774).

An Analysis of the Reduced Morbidity and Mortality Rates After Pancreaticoduodenectomy

Carlos A. Pellegrini, MD; Christopher F. Heck, MD; Steven Raper, MD; Lawrence W. Way, MD

• We examined the course of 51 consecutive patients who underwent pancreaticoduodenectomies between 1979 and 1987. Fifteen patients (30%) had a traditional pancreaticoduodenectomy and 36 (70%) had a pylorus-preserving procedure. Operative blood loss, resumption of oral intake, and time to discharge from the hospital were not different for the two operations. One patient (2%) died of complications of the operation, and 14 patients (27%) had nonlethal intra-abdominal complications. Two patients required reoperation: 1 had a hemoperitoneum and 1 had a breakdown of a choledochoenterostomy. Of the patients undergoing pancreaticoduodenectomy for cancer, 26 (74%) of 35 survived 1 year, 9 (47%) of 19 survived 3 years, and 3 (33%) of 10 patients survived 5 or more years postoperatively. Our data showed that (1) on a service where a large number of these operations is performed, the mortality rate of patients who have undergone a pancreaticoduodenectomy is substantially lower than in the past and that (2) the main reasons for these improved results are greater experience of a few surgeons who perform the procedure regularly and the availability of computed tomographic scans and skilled interventional radiologists, which allows postoperative infection and pancreatic fistulas to be controlled. Although pancreaticoduodenectomy is only palliative in most patients with cancer, it provides the best palliation and the only chance of cure, and the procedure can be recommended when performed in tertiary care centers that possess these elements of success.

***(Arch Surg*. 1989;124:778-781)**

Whipple[1] introduced pancreaticoduodenectomy for carcinoma of the ampulla of Vater in 1935. The indications for the procedure have since been expanded to include other periampullary and pancreatic neoplasms, as well as chronic pancreatitis. Traditionally, pancreaticoduodenectomy has been associated with mortality rates of over 20% and morbidity rates of over 50%.[2,3] Since then, several groups have reported morbidity and mortality rates that are below these high levels.[4-8] Other reports indicate, however, that in some circumstances the mortality rates for this operation remain as high as 30%.[9,10] Therefore, in our study we analyzed our experience with the Whipple procedure to determine the factors that govern the outcome of this operation and why the outcome has improved so dramatically in some hospitals over the past 20 years.

PATIENTS AND METHODS

We examined the course of 51 consecutive patients who underwent pancreaticoduodenectomies at the University of California in San Francisco between January 1979 and December 1987. There were 30 men and 21 women. The patients ranged in age from 29 to 84 years with a mean age of 59 years. Six patients (12%) underwent pancreaticoduodenectomy for pancreatitis and 45 patients (88%) had the procedure for neoplastic disease. Of these 45 patients, 42 (93%) proved to have malignant tumors: there were 19 patients with adenocarcinoma of the head of the pancreas, 12 with adenocarcinoma of the ampulla of Vater, 9 with adenocarcinoma of the distal bile duct, and 2 with adenocarcinoma of the duodenum. Three patients (7%) underwent pancreaticoduodenectomy for pancreatic cystadenomas.

Fifteen patients (30%), 10 with cancer and 5 with chronic pancreatitis, had a traditional pancreaticoduodenectomy. Thirty-six patients (70%), 35 with cancer and 1 with pancreatitis, had a pylorus-preserving pancreaticoduodenectomy.

In the patients with cancer, resection was only performed if there was no overt evidence of extrapancreatic tumor and if it seemed possible to remove the entire lesion. Reconstruction of the gastrointestinal tract was done in the same manner in all patients. The pancreas was sutured end-to-end to the jejunum after mobilizing its posterior surface enough to allow the end of the gland to be intussuscepted into the bowel. When the pancreatic duct was dilated, it was sutured to the edge of the intestine as the anastomosis was done. Stents were not used in the pancreatic duct. The biliary anastomosis was placed 10 cm distal to the pancreaticojejunostomy in end-to-side fashion with absorbable sutures, and stents were not used regardless of the size of the duct. The duodenojejunostomy (or gastrojejunostomy in patients with the traditional Whipple procedure) was placed 30 to 45 cm distal to the biliary anastomosis, and a feeding jejunostomy catheter was routinely inserted 15 to 20 cm further downstream.

All postoperative complications were noted. Particular emphasis

was given to intra-abdominal complications and their management. Follow-up data were obtained through April 1988 from medical records and by telephone contact with patients, their families, and physicians. Follow-up information was available on 47 patients. One patient with pancreatitis and 3 patients with cancer were not available for follow-up.

RESULTS

Twelve (24%) of the 51 patients had had a previous operation on the biliary system; 6 of these patients had undergone exploration (elsewhere) for jaundice within a month of the present admission. Three (6%) patients had had a distal pancreatectomy (for chronic pancreatitis), 2 (4%) had had a distal gastrectomy, and 2 (4%) had had a gastrojejunostomy. Thirty patients (59%) had jaundice preoperatively. The serum bilirubin levels in these patients ranged from 56 to 624 μmol/L, with a mean level of 219 μmol/L.

Of the 45 patients who underwent pancreaticoduodenectomy for tumors, 5 (11%) had a history of cholangitis, 1 had a history of pancreatitis, and 1 had insulin-dependent diabetes mellitus preoperatively. Twenty-three patients (45%) reported preoperative weight loss that averaged 9.2 kg (range, 1.8 to 27 kg).

Coagulation disorders associated with obstructive jaundice were corrected preoperatively; prothrombin times and platelet counts were normal in all patients at the time of surgery. Ultrasonograms were obtained preoperatively in 19 of the 45 patients with cancer: they showed dilated bile ducts in 15 (79%) and a pancreatic mass in only 5 (26%) patients. Computed tomographic scans were obtained in 33 of the 45 patients with cancer: they showed dilated ducts in 20 (60%) and a pancreatic mass in 19 patients (57%). Endoscopic retrograde cholangiopancreatography was done in 30 of the 45 patients with cancer: it showed a blocked pancreatic duct in 6 of 11 patients with adenocarcinoma of the pancreas. In 6 patients, results of an endoscopic biopsy of the periampullary area at the time of endoscopic retrograde cholangiopancreatography was positive for adenocarcinoma. Transhepatic cholangiography was done in 9 patients preoperatively: all had dilated bile ducts. An indwelling catheter was left in the biliary tract in 7 of these patients for preoperative biliary drainage.

Operative blood loss (1330 vs 1400 mL), resumption of oral intake (postoperative day 13 vs 12), and time to discharge from the hospital (postoperative day 20 vs 19) were not different for the traditional and pylorus-preserving operations. One patient (2%) died 32 days after surgery. He had manifested a biliary and pancreatic fistula and became septic in the third postoperative week. Reoperation was performed, the choledochojejunostomy was repaired, and the area of the pancreaticojejunostomy was widely drained. Multiple organ failure developed, however, and the patient died.

Fourteen patients (27%) had other intra-abdominal complications postoperatively. Two patients bled in the immediate postoperative period and one required reexploration of the operative site. She recovered promptly. One patient had a transient postoperative bowel obstruction. Five patients developed a pancreatic fistula. In two of these patients, interventional radiology was needed to replace the drains left at surgery; the other three patients required no manipulation of the drains. The fistulas closed in all patients between the 16th and the 62nd postoperative day. Seven patients manifested intra-abdominal sepsis. Intra-abdominal abscesses diagnosed in five patients by computed tomographic scans were all successfully drained percutaneously by interventional radiology. In four of these patients drainage of the abscess was followed by the development of a pancreatic fistula, which closed spontaneously between the 24th and 54th day. There were no late strictures of the choledochoenterostomy. The Table summarizes the actual survival of the patients who had pancreatectomy for neoplastic disease.

Survival of Patients Who Underwent Pancreatectomy

	Period of Survival*			
Location of Tumor	6 mo	1 y	3 y	5 y
Ampullary carcinoma	11/11	8/8	2/3	1/3
Biliary carcinoma	8/9	6/9	3/5	1/4
Pancreatic carcinoma	16/17	11/16	4/9	1/3
Duodenal carcinoma	2/2	1/2	0/2	. . .
Total, No. (%)	37/39 (95)	26/35 (74)	9/19 (47)	3/10 (33)

*Values represent patients alive as a function of those followed up for that period.

COMMENT

Because of the low long-term survival and the high operative risk associated with pancreaticoduodenectomy, some have questioned whether this operation should ever be recommended as treatment for pancreatic cancer.[11,12] However, we and others[5-7] have shown that the morbidity and mortality rates of this operation have decreased markedly in a number of institutions compared with rates of 20 years ago. Because the mortality rates have not improved universally, however, we were interested in identifying the factors responsible for the sharp decline in our institution. In other words, we wished to pinpoint the principal causes of death and how they have been brought under control.

The thorough review by Jordan[13] has shown that intra-abdominal sepsis, pancreatic fistula, and hemorrhage are the most common serious complications and the most common causes of death after pancreaticoduodenectomy. Consequently, we analyzed the relationship of perioperative management to the prevention of intra-abdominal complications. We also studied the treatment of complications to see how newer methods introduced in the past two decades have influenced the outcome.

Preoperative Factors

Due to the widespread use of computed tomography and endoscopic pancreatography, patients with pancreatic neoplasms undoubtedly come to surgery at an earlier stage of the disease. For example, in one report, the resectability rate rose from 5% for the period from 1973 to 1976 to 21% for the period from 1979 to 1982.[14] The average tumor size in our patients with adenocarcinoma of the pancreas was 3.3 cm, smaller than in previous years. On the other hand, half of our patients had lost more than 10% of their body weight, and in this group the average weight loss exceeded 9 kg.

It is now clear that computed tomography is the most accurate way to stage cancer in the average patient. Ultrasonography and angiography add very little. Endoscopic retrograde cholangiopancreatography is indicated in jaundiced patients, because it allows ampullary neoplasms to be found and biopsy to be performed, and when the pancreatic duct can be opacified, abnormalities are nearly always seen in patients with pancreatic carcinoma. Early in this series, a few patients had percutaneous fine-needle aspiration biopsy before surgery. Because this can be done just as well during the operation—and after observing two hemorrhagic complications following this procedure—we now reserve fine-needle aspiration cytology for unresectable lesions of the body or tail of

the gland or for possible lymphomas. Percutaneous transhepatic biliary decompression was used in seven patients early in this series. Experience has shown, however, that the tangible benefits of preoperative biliary decompression are minimal and are more than offset by the occasional complication,[15-18] so we have abandoned preoperative decompression except for the rare case of obstructing ampullary carcinoma that can be opened up by endoscopic sphincterotomy.

In summary, the diagnosis of pancreatic cancer is being made earlier, but whether the patients are in better shape to withstand pancreaticoduodenectomy is difficult to determine, and whether this has contributed importantly to the drop in operative mortality is questionable.

Operative Factors

Technically, pancreaticoduodenectomy is one of the most challenging operations. The dissection is demanding, blood loss can be substantial, and several anastomoses are required, one of which, the pancreaticojejunostomy, is finicky. The number of pancreaticoduodenectomies performed yearly at our institution has steadily increased. From 1945 to 1970, only 1.5 procedures were done yearly. Three were done in 1979, the first year of this study, 10 were done in 1985, and an average of one was done each month for the past 2 years. Three quarters of the operations in this study were performed by two surgeons who also participated as senior consultants in most of the remaining ones. Similar trends (ie, increasing numbers of cases concentrated into the hands of a few surgeons) have been noted in other institutions reporting similar results.[6,7]

Statistics from the state of New York for the years 1980 through 1986 stand in sharp contrast. The operative mortality rate was found to be significantly lower in hospitals that reported at least four pancreaticoduodenectomies per year, but in hospitals where only one procedure was performed per year, the mortality rate exceeded 30%.[10] Thus, practice improves performance, which we believe also applies to the physicians who perform ancillary services (especially intensive care units, anesthesia, and interventional radiology), as well as the surgeons. The entire team is able to develop skills that help prevent or treat complications.

We have used the pylorus-preserving modification of the Whipple operation for most patients during the last 3 years. Data presented by us[19] and others[20,21] suggest that the quality of life is enhanced by avoiding a gastrectomy and that peptic ulcer disease and gastric motor abnormalities are decreased. Contrary to others,[22] we have not found this procedure to be technically more difficult or prone to postoperative complications. Operative time and blood loss, time to recover gastrointestinal function, and time of discharge from the hospital were similar for the traditional Whipple procedure and the pylorus-preserving operation. Warshaw and Torchiana[23] and others[24] have reported that pylorus-preserving pancreaticoduodenectomy impairs gastric emptying. Only two of our patients had prolonged gastric atony postoperatively, and all patients with pyloric preservation had normal gastric motility within a month of surgery. In fact, gastric emptying was rapid in a group of patients studied during the late postoperative period,[19] and the one patient in our series who required additional surgery for gastric atony had had a traditional Whipple procedure.

Postoperative Management

The principle causes of death after the Whipple procedure are hemorrhage, abdominal sepsis, and pancreatic fistulas.[13,25,26] The decline in postoperative deaths has coincided with improvements in the prevention and management of all three. Postoperative hemorrhage, still cited as the most common cause of death in Jordan's collective review,[13] occurred only twice in our series, and in both cases the hemorrhage was intra-abdominal. In one patient, who otherwise recovered uneventfully, reoperation was necessary to suture a bleeding vessel in the pancreatic bed. We had no cases of gastrointestinal bleeding. Prevention of stress ulceration, better management of intra-abdominal infection, and use of the pylorus-preserving procedure probably contributed to the dramatic improvements in this category.

Although in many reports the precise incidence of sepsis is difficult to ascertain (as it is often reported in combination with pancreatic fistulas), it is a major cause of death after pancreaticoduodenectomy.[13,25,26] Intra-abdominal sepsis developed in eight of our patients, and in four patients it was associated with a pancreatic fistula. This complication was successfully treated without reoperation in all but one patient. A high index of suspicion and use of computed tomography were essential to early diagnosis. Immediate and complete percutaneous drainage of infected collections by interventional radiology, including frequent repositioning of drains, and adequate team management of the fistula tract by the interventional radiologist and surgeon, were critical factors preventing deaths from this complication. With the availability of expert interventional radiologists, reoperation to treat postoperative infection, which was required in 15% of patients in one series,[14] should rarely be necessary in our experience.

All but one of the patients were nourished through a jejunostomy tube while infection was being controlled. We feel that the ability to feed the patient in this way greatly facilitated the management of patients who developed postoperative complications and probably prevented the development of others. We think a feeding jejunostomy should be used in all patients undergoing a Whipple procedure.

Pancreatic fistula, the most common complication of pancreaticoduodenectomy,[13,26] is reported to be fatal in 12% to 40% of cases.[25,27] Death is most often caused by uncontrolled sepsis abetted by the leaking pancreatic juice.[25,26] Pancreatic fistulas developed in nine of our patients. In five it was manifested by drainage of clear, noninfected, amylase-rich fluid through the drain. We believe that control of pancreatic fistulas by closed suction systems placed at the time of surgery helped to minimize the incidence of superinfection. In the other four patients the pancreatic fistula became evident after percutaneous drainage of an intra-abdominal abscess. Whether or not it was associated with intra-abdominal sepsis, every fistula healed without the need for reoperation.

The one patient who died manifested both biliary and pancreatic fistulas. Percutaneous drainage was inadequate and reoperation was required. Despite satisfactory technical correction of the problem and wide drainage of the infection, multiple organ failure developed and the patient died. In retrospect, we think unrealistic hopes of being able to control the fistula percutaneously led to a delay in reoperation. One must be able to identify as early as possible the occasional case where reoperation truly is required.

In summary, our analysis suggests that a high volume of operations done in centers with expert ancillary services, better control of nutrition, a surgical team that is highly experienced with the operation, and a skilled interventional radiologist who is capable of handling the complications are the crucial factors contributing to the low mortality rate observed in our series. As the figures from the state of New York demonstrate, this combination is almost exclusively found in modern tertiary care centers, which is why such institutions can achieve results an order of magnitude better than others.

Percutaneous Cholecystostomy in the Diagnosis and Treatment of Acute Cholecystitis in the High-Risk Patient

Gordon B. Werbel, MD; David L. Nahrwold, MD; Raymond J. Joehl, MD; Robert L. Vogelzang, MD; Robert V. Rege, MD

• We performed percutaneous cholecystostomy in 22 critically ill patients with suspected acute cholecystitis. This procedure accurately diagnosed acute cholecystitis in 17 of these 22 patients and excluded the diagnosis in the other 5 patients. Moreover, percutaneous cholecystostomy stabilized the conditions of 16 of the 17 patients with acute cholecystitis, allowing elective surgery in 8 patients and effectively treating 8 patients who never became surgical candidates. Percutaneous cholecystostomy and bile cultures are useful in the diagnosis and treatment of acute cholecystitis and should be performed in critically ill patients with clinical, laboratory, and radiologic evidence of acute cholecystitis and an excessive risk for cholecystectomy.
***(Arch Surg.* 1989;124:782-786)**

Although elective cholecystostomy is one of the safest abdominal operations, its low operative mortality rate of approximately 0.5%[1] rises significantly when emergency cholecystectomy is performed in patients with failure of other organ systems.[1-4] Thus, when the patient's condition precludes a prolonged general anesthetic, operative tube cholecystostomy, often performed with the area under local anesthesia, has been suggested to be the procedure of choice.[2-4] Cholecystostomy can be lifesaving in these circumstances, allowing the patient's condition to improve so that a safer, elective cholecystectomy may be performed, if necessary. Occasionally, the cholecystostomy is definitive treatment in patients with normal postoperative cholecystograms.[2,3]

Recently, the percutaneous placement of a cholecystostomy tube has emerged as an alternative to surgical placement. Percutaneous cholecystostomy is relatively easy to perform, can be done at the patient's bedside, does not require a large incision, requires only local anesthesia, and does not create significant intraperitoneal adhesions that would hamper subsequent surgical intervention. Thus, it has several theoretical advantages over operative cholecystectomy for the critically ill patient with acute cholecystitis and is undergoing investigation at several institutions.[5-7] In this report, we examine the results of percutaneous cholecystostomy in the diagnosis and treatment of suspected acute cholecystitis in a group of 22 high-risk patients. The results show that percutaneous cholecystostomy is a safe and effective procedure for the diagnosis and management of high-risk patients with acute cholecystitis.

PATIENTS AND METHODS

Patients

Between March 1, 1986, and April 30, 1988, 22 critically ill patients at Northwestern Memorial Hospital, Chicago, Ill, and the Veterans Administration Lakeside Medical Center, Chicago, Ill, were treated with percutaneous cholecystostomy for presumed acute cholecystitis. Patients with common duct stones and obstructive jaundice were excluded because cholecystostomy has been shown to be inadequate decompression under these circumstances. Twenty-three percutaneous cholecystostomies were performed in the 22 patients. One patient refused elective cholecystectomy after resolution of his first episode of acute cholecystitis by percutaneous cholecystostomy; he developed recurrent acute cholecystitis 20 months later. He was successfully treated with a second percutaneous cholecystostomy. The patients treated included 14 men and 8 women ranging in age from 24 to 85 years (mean, 67 years). All patients had been treated with broad-spectrum antibiotics for an average of 4.9 days (range, 1 to 25 days) before percutaneous drainage was attempted. However, many of the patients treated for an extended period had multiple problems and were being treated with antibiotics empirically for fever of obscure origin or for other nonbiliary problems.

The diagnosis of acute cholecystitis was suspected clinically in all patients by the presence of right upper quadrant abdominal pain, tenderness, and an elevated temperature and/or white blood cell count. In addition, 18 patients had abnormal liver function test results. The diagnosis of acute cholecystitis was further supported by the presence of both an abnormal hepatobiliary scan and abnormal ultrasound findings in 10 patients, an abnormal hepatobiliary scan in 7 patients, and an abnormal ultrasound findings in 5 patients. Thus, the clinical diagnosis of acute cholecystitis was supported in every case by at least one, and often by two, imaging studies. In 16 patients,

gallstones were known to be present or were newly identified by ultrasound. The remaining 6 patients were believed to have acute acalculous disease.

All of the patients who underwent percutaneous cholecystostomy had one or more of the following associated disorders: cardiac disease or recent cardiac surgery, pulmonary failure requiring ventilatory support, recent cerebrovascular accident, renal failure, acute pancreatitis, cirrhosis with portal hypertension, encephalopathy, and/or metastatic gastric carcinoma, which are shown in the following tabulation.

Problems	No. of Patients
Coronary artery disease	10
Pulmonary failure	8
Recent cerebrovascular accident	5
Recent cardiac surgery	4
Renal failure	3
Pancreatitis	3
Encephalopathy	2
Cirrhosis	1
Metastatic carcinoma	1

Each patient was classified as class PS-IV (American Society of Anesthesiologists). This rating has been associated with an operative mortality in the range of 8% to 23%,[8-9] confirming that each of these patients was a poor candidate for an emergency operation.

Technique of Percutaneous Cholecystostomy

Percutaneous cholecystostomy was performed under real-time ultrasound guidance. An anterolateral transhepatic approach was used in all cases; the gallbladder was usually entered at the attachment of the gallbladder to the liver, through the upper third of the gallbladder bed. This was done to diminish the risk of bile leakage. Catheter and guide wire manipulation was minimized to avoid bacteremia. Initially, the gallbladder was punctured with an 18- to 21-gauge needle. After the needle tip was sonographically identified in the gallbladder lumen, a small amount of bile was aspirated to confirm the needle position and a guide wire was coiled in the gallbladder lumen. The needle was removed, and a standard pigtail drainage catheter (5F to 8F) was placed into the gallbladder over the guide wire. After catheter insertion and complete aspiration of gallbladder bile, proper position of the catheter was confirmed by the injection of less than 5 mL of contrast material. All tubes were placed to gravity drainage. Bile aspirated from the gallbladder was submitted for Gram's stain as well as aerobic and anaerobic bacterial cultures.

RESULTS

Percutaneous Drainage

Percutaneous cholecystostomy was performed 23 times in 22 patients. The patient who had a second percutaneous cholecystostomy performed for calculous cholecystitis 20 months after his initial drainage responded to percutaneous drainage promptly on both occasions. Later, the second cholecystostomy tube was removed and cholecystectomy was performed without sequelae. Of the remaining patients, dislodgment of the cholecystostomy tube occurred in 5 patients, but it was replaced in 3 patients promptly. Tube replacements were not counted as separate procedures for the purpose of our study, but are considered to be complications of the original percutaneous cholecystostomy.

Despite the extensive preliminary evaluation, including hepatobiliary cholescintigraphy and ultrasound imaging, which indicated that all the patients had acute cholecystitis, five of the patients had sterile bile and showed no clinical improvement with percutaneous cholecystostomy, as is shown in the following tabulation.

Diagnosis	No. of Patients
Patients not clinically improved	
Acalculous cholecystitis	1
Pancreatic abscess	2
Perforated ulcer	1
Pneumonia	1
Postpericardiotomy	1
Total	**6**

Diagnosis	No. of Patients
Patients clinically improved	
Calculous cholecystitis	
Elective operation	8
No operation	5
Acalculous cholecystitis	
Elective operation	0
No operation	3
Total	**16**

Because there was no improvement in their clinical condition or progression of the symptoms in the patients who did not respond to percutaneous cholecystostomy, the diagnosis of acute cholecystitis was questioned and the diagnostic evaluation resumed. Another cause that explained the patients' symptoms, specifically postpericardiotomy syndrome, pneumonia, perforated duodenal ulcer, and, in two patients, pancreatic abscess, subsequently was identified in all five patients. Therefore, in retrospect, none of these patients had acute cholecystitis. It is interesting that the patients in this category were just as likely to have as not to have stones: three had cholelithiasis but not acute cholecystitis, while two were misdiagnosed as having acute acalculous cholecystitis.

Of the remaining 17 patients, 1 with acute acalculous cholecystitis did not respond to percutaneous cholecystostomy within 24 hours. Abdominal pain increased, fever persisted, the white blood cell count increased, and the patient developed signs of peritonitis. Urgent exploratory laparotomy was performed, and a gangrenous gallbladder was found. An emergent cholecystectomy was performed; postoperatively, the patient had no complications and an uneventful recovery. This patient had been treated at another institution for 4 days with symptoms of acute cholecystitis. Thus, percutaneous drainage of the gallbladder was established late in the course of the disease (see previous tabulation).

Of the 16 remaining patients, 13 had cholelithiasis documented by ultrasound, and the presence of gallstones was confirmed in each case by a postcholecystostomy cholecystogram. The remaining 3 patients had acalculous cholecystitis. Only 8 (50%) of these patients had growth of bacteria from the bile cultures performed at the time of percutaneous drainage, most often *Escherichia coli* or *Klebsiella* species. The low yield of bacterial culture was most likely due to broad-spectrum antibiotic treatment of all patients. Resolution of acute cholecystitis was dramatic in all of the patients and occurred within 24 hours of percutaneous drainage (see previous tabulation).

Eight of the 16 patients whose conditions were successfully stabilized by percutaneous drainage had marked improvement in their medical condition and subsequently underwent elective cholecystectomy between 7 days and 20 months after the initial drainage. Remarkably, there was no operative mortality in this group of 8 patients; the only morbidity was an uncomplicated perioperative myocardial infarction in 1 patient. Three of the remaining patients died of worsening of their medical condition at 7 days, 13 days, and 3 months after drainage. In each case, the signs and symptoms of acute cholecystitis disappeared promptly after cholecystostomy, and there was no evidence that biliary tract disease or persistent cholecystitis contributed to their deaths. This was confirmed at autopsy in 1 patient. Rather, each of these deaths was directly attributed to progression of the primary medical problem.

The remaining five patients had resolution of acute cholecystitis but did not undergo elective operation. Their cholecystostomy tubes were removed electively after 7, 8, 20, 45, and 180 days. Three of these patients had acalculous cholecystitis confirmed by a normal cholecystogram after the proce-

dure and remained symptom free at 2, 10, and 22 months after removal of their cholecystostomy tubes. Two patients with calculous disease were very poor candidates for elective cholecystectomy; they were observed without treatment. Fortunately, both remained symptom free at 3 and 14 months following removal of their gallbladder drainage tubes and have required no further therapy for biliary tract disease.

Complications of Percutaneous Drainage

All complications of percutaneous cholecystostomy in these 23 procedures performed in 22 patients were reviewed and these complications are shown in the following tabulation.

Complication	No. of Patients
Colonization of bile with new bacteria	6
Catheter dislodgment	5
Bile leakage (all contained)	3
Duodenal puncture	1
Incorrect catheter position	1

Injection of contrast material through the needle in 1 patient demonstrated a duodenal puncture; the needle was removed, placed correctly, and no complication of duodenal injury was evident. The cholecystostomy tube was incorrectly positioned in another patient and was demonstrated when contrast material was injected immediately after placement; this was easily corrected by repositioning the tube, and the patient had no problems after the procedure. Three patients developed small, asymptomatic bile leakage that became localized over the dome of the liver. Six patients had colonization of their bile with new organisms. The bile collections resolved spontaneously, and no patient developed a clinically significant infection, ascending cholangitis, liver abscess, or sepsis. Finally, the catheter was accidentally dislodged in 5 patients; in 3, the tube was replaced promptly because their episode of acute cholecystitis had not fully resolved. All of these complications were minor because none significantly altered the hospital course of any of the patients.

Three patients died within 30 days of the percutaneous drainage, for a 30-day mortality of 13.6%. However, no death was directly attributable to the percutaneous cholecystostomy or to persistent biliary tract disease.

COMMENT

The recent development of ultrasound and computed tomography has allowed accurate, noninvasive imaging of intra-abdominal and intrathoracic organs and the localization of pathologic processes. Besides improving the preoperative diagnosis of intra-abdominal problems, the accuracy of these imaging techniques has led to several nonoperative but therapeutic procedures, including percutaneous drainage of intra-abdominal abscesses and pancreatic pseudocysts,[10] percutaneous nephrostomy,[11] and percutaneous transhepatic drainage of the obstructed biliary tract.[12] It is not surprising, then, that a cholecystostomy catheter can be placed safely into the gallbladder via the transhepatic approach. Percutaneous transhepatic cholecystostomy has been performed to gain access to the gallbladder for contact dissolution of cholesterol gallstones with the agent, methyl tert-butyl ether,[13] and is becoming an alternative to surgical cholecystostomy at some institutions for decompression of the gallbladder in acute cholecystitis.[5]

Since the first report of the treatment of suspected acute cholecystitis by Radder in 1980,[14] the use of percutaneous cholecystostomy has been documented in 105 patients in the English literature.[14-29] Adding our 22 patients to this experience provides a total of 127 patients for review, the results of which can be seen in the following tabulation.

Key Factors	Ratio of Patients	% of Total
Diagnostic accuracy	125 of 127	98
Success rate	113 of 114	99
Morbidity	29 of 114	25
Mortality	11 of 114	10

Of this group, 114 patients had acute cholecystitis, while 13 patients did not. Percutaneous drainage of the gallbladder was diagnostically accurate, confirming or excluding the diagnosis in 98% of these patients, and successfully treated 99% of the patients with acute cholecystitis. The only reported failure of this technique was in our series. The overall mortality rate of 9.6% (and our rate of 13.6%) compares favorably with the mortality rates reported in the literature for surgically placed tube cholecystostomy, which ranges between 6% and 28.5%,[2,30] especially because only 3 (2.6%) of 114 patients died as a consequence of the procedure. A significant number of complications were reported only by vanSonnenberg[28] and us, but were clinically insignificant in almost all patients. However, intraperitoneal hemorrhage (3 patients) and hypotension due to sepsis and/or vasovagal reactions (5 patients) have been reported, and represent potentially serious complications of this procedure. Their occurrence can be minimized by careful attention to technical details, including the possible use of atropine sulfate before drainage.

Our results in these 22 critically ill patients were comparable with the world experience. Percutaneous cholecystostomy was performed with minimal stress to the patient, resulted in very few significant complications, and caused prompt improvement in all but 1 of the patients. The resolution of acute cholecystitis was followed in most cases by marked improvement of the patient's overall medical condition. More remarkable was the long-term outcome of these patients: 8 patients eventually underwent elective cholecystectomy with no deaths, 2 very ill patients had control of their biliary tract disease for 3 and 7 months, and 3 patients with acalculous cholecystitis required no further therapy and remained free of symptoms at 2, 10, and 22 months. In addition, it excluded the diagnosis in 5 patients, avoiding an unnecessary operation.

The fact that 23% of our patients did not have acute cholecystitis, despite clinical and radiologic evidence of that problem, requires comment. This should not detract from the value of ultrasound and hepatobiliary scanning in this disease, but it does reflect the difficulties encountered in establishing this diagnosis in a critically ill patient. Severely ill patients often have altered states of consciousness and may not exhibit the typical clinical findings of acute cholecystitis. The signs and symptoms can be masked by pain from recent operations or traumatic injuries, by pain medications and sedatives, or by antibiotics given for other reasons. Moreover, asymptomatic or mildly symptomatic gallstones are commonly present, raising the question of a biliary cause for fever and/or abdominal pain. Finally, the combination of sepsis, narcotic administration,[31] and prolonged fasting, which is frequently seen in patients receiving total parenteral nutrition, leads to gallbladder stasis, gallbladder distention, and viscous bile, if not to frank gallbladder bile sludge or stones.[32,33] The radioactive agent used in hepatobiliary cholescintigraphy often cannot enter the gallbladder under these circumstances, and false-positive scans result.[34] It is crucial that an accurate diagnosis of acute cholecystitis be made in critically ill patients to avoid an unnecessary operation. Percutaneous cholecystostomy was helpful in this regard because it excluded acute cholecystitis in five of our patients.

We are impressed with the ease of performance and the safety of percutaneous cholecystostomy, and believe it is the procedure of choice in critically ill patients with suspected acute cholecystitis. We would urge early performance of per-

cutaneous cholecystostomy in the critically ill patient who has clinical, laboratory, and radiologic evidence of acute cholecystitis and who has an excessive operative risk. The results of bile culture and the clinical response to percutaneous drainage may have diagnostic value in patients who do not have acute cholecystitis, while drainage of the gallbladder is therapeutic in almost all patients who do. We speculate that early performance of percutaneous cholecystostomy might be most beneficial to patients with acute acalculous cholecystitis since it definitively treated three of four of our patients with this problem.

Discussion

CARLOS A. PELLEGRINI, MS, San Francisco, Calif: We have used a similar approach and believe that percutaneous transhepatic cholecystostomy is an excellent way to diagnose and treat acute cholecystitis in critically ill patients. My comments emphasize three specific areas.

First, with respect to indications of the procedure, you included a number of patients with acute acalculous cholecystitis. This form of acute cholecystitis is particularly prone to necrosis of the gallbladder wall and this happened in one of your patients. Is there any way to select these patients or are there any clues that may tilt the balance toward a laparotomy rather than a percutaneous approach? My feeling is that there are none and that the key is close observation after the catheter has been introduced into the gallbladder. Early operation should be performed if the patient's condition does not improve.

Second, after a few days of catheter drainage, and when the patient's underlying condition allows, we perform cholecystocholangiography to study the cystic and common bile ducts. In a few patients with severe underlying conditions and high risk for a subsequent elective cholecystectomy, our interventional radiologists were successful in removing all the stones from the gallbladder after dilating the cholecystostomy tract. These patients have done well. In another patient with concomitant choledocholithiasis and unrelenting signs of infection, our radiologists were able to negotiate a catheter through the cystic duct in to the common bile duct and effectively treat the underlying cholangitis. This patient did well but eventually required a cholecystectomy for a persistent biliary cutaneous fistula. Do you routinely perform contrast studies of the biliary tract? Do you have any experience with percutaneous cholecystolithotomy? Have you used stone dissolution agents? Do you always advise elective cholecystectomy?

Third, you had five patients who you decided did not have acute cholecystitis because they did not respond to this form of treatment. You were able to diagnose another cause that explained their clinical course. How sure are you that they did not have acute cholecystitis and just failed to respond? Could you give us more information regarding their course with specific reference to the biliary tract? Have any of them been investigated after discharge for evidence of biliary tract disease?

ARTHUR J. DONOVAN, MD, Los Angeles, Calif: If an ultrasound shows a pericholecystic fluid that could be consistent with a pericholecystic abscess, would you still perform a percutaneous cholecystostomy?

KENNETH J. PRINTEN, MD, Evanston, Ill: I am a bit distressed to learn that a procedure that has a complication rate of 7%, albeit minor complications, is recommended for the treatment of the critically ill patients. The time of precholecystostomy antibiotic treatment was part of your treatment protocol or a representation of delay in either referral or recognition of the diagnosis. From the listing of the diseases that rendered these patients American Society of Anesthesiologists category IV, can you determine which situations would

clearly contraindicate any other therapy by percutaneous cholecystostomy?

DONALD J. FRY, MD, Albuquerque, NM: This article represents the continuing ongoing prejudice that exists in the literature, which is, anything that avoids an incision is always better than something that requires sticking a needle into someone. I would challenge the validity as it relates to percutaneous cholecystostomy. With a small incision with the area under local anesthesia, one can look at the gallbladder and see whether it is dead or not, which in patients who have had a myocardial infarction or congestive heart failure is a real issue. A well-controlled surgical incision performed with the area under local anesthesia will allow you to evacuate the stones, do a liver biopsy, and look at the pancreas. You can assess whether there is a perforated ulcer. You don't have to find out about it days later. This study is interesting and it shows there can be a triumph of technology over incision, but it has not proved the point that technology is superior to a well-planned, well-executed cholecystostomy using local anesthesia. Before everyone goes home and takes this procedure to give yet an additional piece of turf to the radiologist, it is appropriate that perhaps we have a multicenter, randomized trial to really address whether this is something new and better or if it is just something new.

RICHARD A. PRINZ, MD, Maywood, Ill: Your series is much like our experience. The thing that makes our patients class IV in most cases is cardiac disease or a recent myocardial infarction or coronary artery surgery. We have taken a different track. We have not shunned technology but have looked to our cardiologists, cardiac surgeons, and anesthesiologists to develp a group approach. By inserting the intra-aortic balloon pump, we have been able to improve the status of these patients who have serious cardiac disease. Have you had any experience with this approach? We have performed it in 16 patients with no operative mortality from the balloon pump. Two patients have died of arrhythmias on days 2 and 9 after the operation. The rest of the patients are alive without their gallbladders.

GEORGE B. MARKLE IV, MD, Carlsbad, NM: Was there a sex predominance in this series? It seems in my limited experience that men with acute cholecystitis are far more apt to experience perforation and have difficulties than women who usually will respond and "cool off" with medical treatment.

Dr NAHRWOLD: Mr Pellegrini is concerned about the five patients in whom the percutaneous cholecystostomy was done and subsequent events showed that they did not really have acute cholecystitis. Any endeavor to treat patients such as these by a technique where the gallbladder cannot be seen or a biopsy cannot be performed will be fraught with unnecessary procedures. At this point, we cannot get around this problem.

With regard to how the patients are managed after the percutaneous cholecystostomy and general improvement, we obtain a cholangiogram and cholecystogram through the catheter. A variety of techniques can be used to get rid of the stones at this time. In our view, all of them are highly experimental and should be done only under specific research protocols.

One method, of course, is treatment with methyl tert-butyl ether. Patients who have had recent inflammation of the gallbladder should not be given this therapy. Another method is dilatation of the tract over time and a manual extraction of the stones. Lithotripsy may also be used, and the fragments can then be blushed out or manually extracted.

Mr Pellegrini also made reference to the fact that we need to work harder to make the diagnosis of acute cholecystitis. The problem is that we do not have firm criteria for the ultrasonic diagnosis, and HIDA scans may be falsely positive in patients in intensive care units whose gallbladders have not contracted for some time.

Dr Donovan asked whether we would do percutaneous cholecystostomy in a patient who showed a pericholecystic fluid collection. In general, yes, but that depends on what that fluid collection is like. If it is clearly an abscess, we could not perform a percutaneous cholecystostomy.

Some reference was made to the fact that there was a delay of 5 days from the time of diagnosis to the percutaneous cholecystostomy, and we apologize for this misperception. It was not a delay of 5 days before percutaneous cholecystostomy was done because they had other diseases, such as adult respiratory distress syndrome and other infections.

This is a procedure that is in evolution and appears to be useful in very ill patients who are in the intensive care unit. Many of these patients are on ventilators. They have cardiopulmonary support devices, and even transport is extremely difficult.

The fact that our medical and radiology colleagues seem to find it more sensible to do a less invasive procedure if one is available means that surgeons need to become involved in these procedures. I believe that if we are to prevent the further erosion of general surgery, we as surgeons need to be aggressive and need to participate in the new procedures that are being performed. We need to understand, to participate in, and to have hands-on experience with percutaneous cholecystostomy, biliary lithotripsy, and the like.

Endoscopic Cholangiography and Stone Removal Prior to Cholecystectomy

A More Cost-effective Approach Than Operative Duct Exploration?

Greg Van Stiegmann, MD; Nathan W. Pearlman, MD; John S. Goff, MD; John H. Sun, MD; Lawrence W. Norton, MD

• Would economic benefit result from performing endoscopic cholangiography and removal of common bile duct stones prior to cholecystectomy in patients who are suspected preoperatively of having choledocholithiasis? In this study, 173 patients had cholecystectomy and 30 (17%) had common bile duct exploration. Records of these patients were reviewed as were those of 31 patients who had only endoscopic cholangiography and endoscopic stone removal. Cost estimates were based on local charges. Cholecystectomy with common bile duct exploration was $6730 more per patient than cholecystectomy alone. Endoscopic cholangiography and endoscopic stone removal was 87% successful in removing duct stones. Had endoscopic cholangiography and endoscopic stone removal been performed preoperatively in patients undergoing cholecystectomy who had suspected choledocholithiasis, 21 of 30 common bile duct explorations could theoretically have been eliminated. This would have saved $85 526 or $2851 per patient undergoing common bile duct exploration. Our analysis suggests that patients who require cholecystectomy and have suspected choledocholithiasis may be treated more cost-effectively by performing endoscopic cholangiography and endoscopic stone removal immediately prior to cholecystectomy than by cholecystectomy and operative common bile duct exploration.

***(Arch Surg.* 1989;124:787-790)**

Cholecystectomy, operative cholangiography, and common bile duct exploration (CBDE) are standard treatments for patients with symptomatic cholelithiasis who harbor common bile ducts stones. Endoscopic retrograde cholangiography (ERC), sphincterotomy, and stone removal is accepted for high-risk patients with symptomatic choledocholithiasis and for those who have retained common duct stones following cholecystectomy. Preoperative endoscopic cholangiography and stone removal are seldom considered for otherwise healthy patients who require cholecystectomy and have suspected choledocholithiasis. The purpose of this study was to attempt to determine if economic or clinical benefit might result by subjecting otherwise healthy patients who required cholecystectomy and had suspected common bile duct stones to preoperative ERC and endoscopic stone removal (ESR) followed by cholecystectomy alone.

MATERIALS AND METHODS

Hospital records of 173 patients who had elective or semielective cholecystectomy and cholecystectomy with operative common bile duct exploration (C + CBDE) during a recent 18-month period were selected for detailed examination. Thirty-one additional patients, who had previously undergone cholecystectomy or were high risk, considered candidates for endoscopic common bile duct clearance without cholecystectomy, and had only ERC/ESR, were also reviewed. Hospital costs and fees were based on local charges. Cost differences were generated by determining excesses in hospital stay, operating room time, and hospital and physician fees. Minor complications were defined as any untoward non–life-threatening events that prolonged hospitalization. Major complications were defined as life-threatening events or problems whose resolution required reoperation or major nonoperative procedures. Statistical analysis was by χ^2 and Student's *t* tests.

RESULTS

Thirty (17%) of 173 patients undergoing cholecystectomy had CBDE. Twenty-four of the 30 patients undergoing C + CBDE had the choledochotomy because of choledocholithiasis suspected on operative cholangiography and 16 had stones (67% positive exploration). Six additional patients undergoing cholecystectomy underwent CBDE for other reasons, including distal common duct stenosis suspected on operative cholangiography (n = 3), bile duct injury during cholecystectomy and operative cholangiography (n = 2), and duct exploration because the cholangiogram catheter was inadvertently sheared off while inside the common duct and required operative removal (n = 1).

Patients undergoing cholecystectomy and C + CBDE were comparable for height, weight, sex, preoperative hospital stay, and number of previous upper abdominal operations. Although patients undergoing CBDE had more than twice the incidence of major postoperative complications, a statistically significant difference was not present (Table 1). Postoperative hospital stay, minor complication rate, mean operating time, and age were significantly greater in patients undergoing C + CBDE (Table 2). Increased length of postoperative hospitalization, operating room time, and physician and hospital fees (radiology, anesthesiology, etc) resulted in a mean calculated increased cost per patient of $6730 for C + CBDE when compared with cholecystectomy alone (Table 3).

Among the 31 patients who underwent ERC and attempted stone removal during the same 18-month period, 87% had all common bile duct stones removed successfully. Two of these patients had suspected perforation and were successfully treated by laparotomy and simple drainage of the periductal area. Hospital facility and professional charges for ERC alone were $1150. If stones were present in the common duct, the additional cost for ESR was $696 (Table 4).

Thirty-four of the 173 patients who had cholecystectomy were suspected preoperatively of having choledocholithiasis based on ultrasound diagnosis of common duct stones or the presence of one or more laboratory criteria, such as persistently elevated serum bilirubin, alkaline phosphatase, amylase, and transaminase levels. Thirty-four (19.6%) of the 173 total patients had one or more of these criteria immediately preoperatively and 24 (70%) of these 34 patients underwent CBDE. Ten were not explored because of negative cholangiograms. Sixteen of the 24 who had CBDE had choledocholithiasis (16/34, 47% of those suspected preoperatively). Six other

†If suspicion of choledocholithiasis had been used as the indication for preoperative ERC/ESR, 34 patients would have had ERC.

‡The 24 patients in whom stones were suspected would have had attempted ESR.

§Nine patients would still have required CBDE, including six who were not suspected of having choledocholithiasis preoperatively and three in whom ESR theoretically failed.

patients who underwent CBDE were not thought to require CBDE by preoperative clinical or laboratory evaluation.

Had the 34 patients in whom choledocholithiasis was suspected undergone preoperative ERC,21 (87%) of 24 who had CBDE could theoretically have been spared both operative cholangiography and CBDE either by successful ESR or negative endoscopic cholangiogram. A total of 9 patients would still have required operative CBDE (3 who would theoretically have failed ERC/ESR and 6 who were not thought to require CBDE preoperatively). Had patients been treated by precholecystectomy ERC/ESR, a net saving of $85 526 or $2851 per patient who had CBDE could have resulted (Table 5).

COMMENT

This study confirms previous reports that C+CBDE is associated with significantly greater length of hospitalization, operating room utilization, and complications than cholecystectomy alone.[1] These differences result in an additional calculated cost of over $6500 for patients who have operative C+CBDE. Cholecystectomy and CBDE is currently the treatment of choice for otherwise healthy patients who have symptomatic gallbladder disease and choledocholithiasis. The mortality rate for CBDE in such patients is approximately 1%.[2,3] Mortality increases with age and increasing medical problems, and may rise to as high as 5% to 12%.[3,4] Postoperative sequelae of CBDE include retained stones, bile duct strictures, and inadvertent ductal injury. A 5-year follow-up of over 200 patients who underwent cholecystectomy and duct exploration at Mayo Clinic, Rochester, Minn, revealed that 5% had recurring biliary problems.[5] Other studies concur that the risk of long-term biliary complications following CBDE ranges from 5% to 10%.[6,7] Studies of patients who have had CBDE followed by choledochoduodenostomy or sphincterotomy (as would occur with ESR) suggest that patients so treated may have a lower incidence of long-term biliary problems than those who do not have a ductal drainage procedure.[7,8]

Endoscopic cholangiography, sphincterotomy, and ESR has evolved rapidly during the past 10 years. This procedure is now widely employed and accepted for patients who have

retained common bile duct stones following prior cholecystectomy and in high-risk patients who have asymptomatic gallbladder stones but symptom-producing choledocholithiasis.[9] Success of ERC and endoscopic sphincterotomy and ESR has been reported at 85% to 90%[10-13] and in this series was 87%. Long-term success of endoscopic duct clearance appears similar to that for operative duct exploration with 5% to 10% of patients developing recurrent biliary problems, the majority of which can be managed endoscopically.[13,14] Mortality associated with ESR is approximately 1% and complications such as perforation, bleeding, cholangitis, and pancreatitis occur in 8% to 10% of patients.[12-16] Operation is required to treat complications of endoscopic sphincterotomy in 1% to 3% of patients.[13,17]

Preoperative ESR followed by cholecystectomy has been prospectively compared with C + CBDE by Neoptolemos et al.[18] These British investigators concluded that there was no statistically significant difference in the clinical outcome between the two groups, although the endoscopic group had a higher incidence of major complications, primarily septic in nature, resulting from incomplete duct clearance. Such complications may have been ameliorated if not totally eliminated had patients in this study been subjected to operation immediately following the endoscopic procedure instead of waiting a median of 5 days (range, 1 to 117 days) to perform cholecystectomy. More importantly, from the perspective of economic analysis, these authors showed a statistically significant reduction in total hospital stay of 5 days in the endoscopically treated patients. The economic impact of such a reduction in the British National Health Service may be of less importance than similar reductions in the more cost-conscious United States. Another recent report from Miller and associates[19] examined patients with choledocholithiasis treated both surgically and endoscopically and concluded that the results of endoscopic and operative treatment, with regard to success of treatment, morbidity, and mortality, were similar. These authors also demonstrated that hospital stay was significantly less for patients treated endoscopically, although no mention was made of economic impact.

In view of the greater utilization of resources and resulting increased cost that appear to accompany operative duct exploration, it seems reasonable to consider endoscopic duct clearance in conjunction with operative removal of the diseased gallbladder in otherwise healthy patients. Endoscopic cholangiography provides a precise delineation of the biliary system that may alert the surgeon to potentially treacherous anatomical variations before the incision is made. The status of the papilla and presence of noncalculous causes of biliary obstruction may be determined preoperatively. The quality of cholangiograms obtained endoscopically in the radiology department is superior to the average operative cholangiogram. Multiple and magnified views, repeated injections, pharmacological manipulations, and different patient positions are all more readily accomplished during ERC than in the operating room. If common duct stones are present, the endoscopist and radiologist can usually be confident in determining if satisfactory duct clearance has been achieved both by radiological imaging and actual visualization of extracted calculi. Incomplete endoscopic duct clearance would signal the need for prompt operative duct exploration. Moreover, timing of the elective operation to follow endoscopic manipulation as closely as possible should prevent the occurrence of endoscopy-related cholangitis and minimize the impact of other complications by allowing rapid surgical treatment. Further savings in operating time should also be realized by eliminating the need for operative cholangiography in those cases in which endoscopic duct visualization and/or treatment has been successful. The single potentially negative technical aspect of operation following closely on endoscopy may be the inconvenience of dealing with distended loops of bowel resulting from insufflation of air during the endoscopic procedure.

Operative treatment of calculous disease of the biliary tract has, during the past 100 years, been refined to a successful and safe, yet increasingly costly, endeavor. Endoscopic treatment is still in its developmental stage. Our analysis has shown that C + CBDE is associated with longer hospitalization and operating time and, hence, greater cost than cholecystectomy alone. Endoscopic cholangiography and stone removal has been shown to be effective and efficient treatment for patients who have common bile duct stones. Otherwise healthy patients with symptomatic cholecystitis and a suspicion of choledocholithiasis may be more economically treated by preoperative ERC and (if common duct stones are present) ESR immediately prior to cholecystectomy than by operative CBDE performed at the time of cholecystectomy. A prospective study with emphasis on the cost-effectiveness of the two alternatives is warranted.

Discussion

LAWRENCE J. KOEP, MD, Phoenix, Ariz: The authors have presented an extremely provocative report. Among endoscopists there is general agreement to employ ERC to minimize the need for "exploration" of the common bile duct. This is particularly true in those patients with clinical or laboratory indications for duct exploration. How much would ERC alone have reduced costs by eliminating your negative duct explorations and avoiding your iatrogenic complications?

Endoscopic stone removal, particularly in healthy patients, is a quantum jump from current endoscopic practice. Perhaps it is justified and a prospective study is warranted. Since ESR requires a sphincterotomy with a cautery papillotome, the complications, as you note, are perforation, bleeding, and pancreatitis. The mortality of

this procedure alone, in experienced hands, is 1%. In high-risk patients, this mortality is acceptable since it has allowed 60% of these patients to have no further surgery. However, to add this morbidity and mortality to low-risk patients who are then also going to face the risk of cholecystectomy may not be appropriate. You did not mention pancreatitis in ESR as other studies have reported. Were you spared? Any hints on avoiding it?

Finally, with the biliary lithotriptor showering stones down on the common duct, the interaction of surgery and endoscopy promises to become only more complex.

L. BEATY PEMBERTON, MD, Kansas City, Kan: I think we can agree with the authors that exploring the common bile duct does take more operative time and generates a significant increase in morbidity and probably mortality than performing a cholecystectomy alone. These findings corroborate the results of other studies.

Although the suggestion that we should try ERCP removal of common bile stones prior to cholecystectomy because it is cheaper and has fewer complications may, in fact, be correct, this report does not present any convincing evidence to support this conclusion. Surgeons should not change their usual method of CBDE for stones based on this unsubstantiated speculation about possible cost savings.

A comparison between the increased cost of removing a common bile duct stone during a cholecystectomy in one group of patients and another group who do not have removal of a common bile stone by ERC is both inappropriate and misleading. These two groups are so different that they cannot be compared.

Since the authors do not try to use any statistical analyses on these dissimilar groups, I suspect they acknowledge this point and have called for a prospective study.

What this report does show is that the operating room is much more expensive per minute than the room we use to perform ERC and that hospital beds are more costly than beds at home. Neither of these findings is a sufficient reason to change our practice of how to deal with common bile duct stones.

To make a meaningful comparison and to substantiate their conclusion, they need to do a prospective study on patients with gallstones in the gallbladder and in the common bile duct, and randomize them into two groups, one treated by C + CBDE and one treated by ERC removal of the common bile stones followed by cholecystectomy. Show us that this suggested method is as effective and safe as our standard method, then prove that the cost savings is real and not theoretical. Substantiate this conclusion by examining the patient's hospital bills and comparing that rather than costs gleaned from different sets of patients with different hospital costs.

FRANK R. LEWIS, JR, MD, San Francisco, Calif: It appears from the results presented that 80% of the increased cost in the CBDE group was the additional 4½ days in the hospital. I would like to ask if that stay was warranted by problems with the patients or were the patients simply being kept in because they had a T-tube and drain in place? If the latter is the case, then these patients could have been sent home earlier, obviating that cost entirely and perhaps resulting in an even lower cost than the alternative. I would appreciate a detailing of that in the discussion.

EBERHARD A. MACK, MD, Madison, Wis: I rise to say a word of caution. If we would employ an endoscopic procedure in young patients, we actually would add this 1% mortality and at least a 7% complication rate to the actual overall picture for the patient. In young patients, a properly done C + CBDE where the patient would leave the hospital 4 days after the procedure is probably in the interest of the patient and would not be subject to cost-saving procedures.

There is a great importance in selecting the patients. If we consider endoscopic sphincterotomy with stone removal in the high-risk elderly patient, this may be appropriate, especially in those patients who present with ascending cholangitis who are too sick to undergo general surgery.

There is also a problem with the discrepancy of the stones found in the common duct and what the gastroenterologists can extract through the narrow portion of the duct and through the pancreatic head. I am not quite sure that money should always dictate to the disadvantage of good patient care.

FRANK T. JORDAN, MD, Las Vegas, Nev: I have several questions about the actual fairness of extrapolating your data from a cholecystectomy series up to an ESR series. You are selecting patients before the ESR based on age and severity of illness. In the cholecystectomy series you may be selecting them on the size of stone.

In a series presented at this organization several years ago, we reviewed 150 patients who underwent ESR, and one of the limiting factors was stone size. If you have a 2-cm stone, then you can't remove it endoscopically, resulting in a minimal success rate with this group. How many patients in your C + CBDE group had sizeable stones? That may reflect the 3-hour mean time for CBDE, which seems excessive.

In our study, the only statistically significant difference when C + CBDE was compared with ERC and removal of stones was if the two procedures were done in tandem. How many patients in your series had a tandem procedure done—not just a cholecystectomy and stone removal but a common duct and stone removal?

R. DOUGLAS YAJKO, MD, Glenwood Springs, Colo: Living in Colorado, I can assure you that Dr Van Stiegmann gets to talk to the internal medicine people, and in general I think they would favor an approach like this. Once the internist sees the patient, there is a consultation fee as well as the fees regarding the ERC, which is performed by the gastroenterologist. The possibility of getting post-ERCP pancreatitis is certainly real, and in this instance, the patient gets admitted for a few days' stay. The internist gets an admission fee as well as the daily fee for the hospital days. I feel that the fees generated by the internist, as well as the increased hospital stay prior to their cholecystectomy, are not factored into this study. Unless these are factored in, this has to be looked at as added cost to the patient rather than a positive effect.

DR VAN STIEGMANN: I would like to thank the discussants for their thoughtful comments and begin by addressing Dr Koep's question as to whether ERC alone may have reduced the cost of the negative duct explorations. This study commenced with the notion that we could perhaps reduce the cost of cholecystectomy by eliminating the operative cholangiography by doing an endoscopic cholangiogram. The answer to that is no, we cannot do it more cost-effectively, even in a university setting where an operative cholangiogram costs about $600.

Dr Koep commented on the mortality of ESR, which is approximately 1% and higher in some other series. It is true that there is added mortality when dealing with the duct endoscopically or operatively.

A very recent series from Seattle by Miller and associates compared CBDE (in patients who had prior cholecystectomy) vs ERC and ESR. The morbidity and mortality of the two techniques were equal. The only difference was that the operative group spent a lot longer in the hospital.

What about pancreatitis? I cannot comment from our retrospective study. I can comment from our ongoing prospective study. It has not been a problem thus far, but theoretically it certainly could be. Dr Pemberton commented on the unsubstantiated speculation involved in this report, and I agree fully. We cannot advocate (nor do we) that ERC and ESR should be used preoperatively in the otherwise healthy patient at this time.

This must be studied, and even if it is less expensive, we must balance out what is best for the patient. We do not advocate that the current practice be changed. In a British study published about a year ago doing exactly what we have proposed, they found no significant difference in complications or hospital stay. However, because of the British system and the way they tallied their results, they did not feel the difference warranted recommending one technique over the other.

Dr Lewis correctly associated 80% of the increased cost in our common duct with prolonged hospital stay. Our mean hospital stay for the CBDE group was approximately 9 days. All of these patients were hustled out of the hospital as quickly as possible. None were kept because they had a T-tube. Those numbers may even be shorter today. I doubt that those days could be lessened.

Dr Jordan commented very appropriately about the size of the duct stones. Larger stones are more difficult to remove endoscopically. The two patients in our study would have been excluded because of the size of the stone had they in fact had endoscopic treatment preoperatively.

The comment about the average operating time of 3 hours is interesting. Nobody in the room would admit to 3 hours of operating time for a C + CBDE. In our hospital, the patient is charged from the time he hits the door until the time he leaves the room. So that while the C + CBDE may take 1½ to 2 hours, there is some fiddling at the front and back ends. In the meantime, the clock is running and the dollars are mounting up.

Less Is Better

The Diagnostic Workup of the Patient With Obstructive Jaundice

Richard Olen, MD; Jack Pickleman, MD; Robert J. Freeark, MD

• The typical patient with suspected obstructive jaundice is often subjected to an extensive preoperative workup on the premise of providing surgeons with information that will aid them at exploration. A 15-year review of 83 patients with obstructive jaundice from the common periampullary carcinomas was carried out and indicated that obtaining such information was unnecessary, unsafe, costly, and time-consuming. It is recommended that the patient with a medical history and liver function test results suggestive of obstructive jaundice should undergo an abdominal ultrasound study. If this discloses distal bile duct obstruction, no further tests are necessary in most patients and the operation should be carried out promptly.

(*Arch Surg.* 1989;124:791-795)

When a patient presents with jaundice, a physician will generally be able to categorize it as prehepatic, hepatic, or posthepatic in origin after interpreting basic liver function test results. What generally follows in a patient suspected of harboring obstructive jaundice secondary to a malignant tumor is a costly and time-consuming series of tests designed to "help the surgeon" when he or she ultimately operates on the patient. It appeared to us that most of these tests were superfluous and that even when they provided diagnostic information preoperatively, the surgeon still relied on inspection, palpation, and mobilization of structures to reach a decision regarding resection vs bypass. The purpose of this study was to evaluate this bias and document the value of the commonly ordered preoperative tests in patients with obstructive jaundice.

METHODS

A 15-year retrospective review of the charts of all patients presenting with obstructive jaundice secondary to the common periampullary malignancies (ie, pancreas, common bile duct, and Vater's ampulla) was carried out. Patients with no jaundice with these disorders were excluded, as were those patients with benign bile duct obstruction or malignant obstruction originating in the proximal biliary tree. Lastly, patients with metastatic carcinoma to the porta hepatis were excluded.

Read before the 96th Annual Meeting of the Western Surgical Association, San Diego, Calif, November 14, 1988.

Reprint requests to Department of Surgery, Loyola University Medical Center, 2160 S First Ave, Maywood, IL 60153 (Dr Pickelman).

Only patients treated at the Loyola University Hospital, Maywood, Ill, were included in this study. In all, 83 patients were identified with their diagnoses shown below.

Diagnosis	No. of Patients
Carcinoma of the pancreas	60
Carcinoma of the bile duct	19
Carcinoma of the ampulla	4
Total	83

Fifty of these patients were men and 33 were women. Ages ranged from 30 to 94 years (mean age, 64 years). All preoperative tests were tabulated along with the results, accuracy rates, and complications.

RESULTS

When patients were initially admitted to a medicine rather than a surgical service, significantly more preoperative tests were carried out and the duration of preoperative testing was prolonged to 16.0 days vs 7.7 days.

Fifty-three of the 83 patients underwent an abdominal ultrasound study (US) with the results shown below.

Findings	No. of Patients
Normal	4
Nondiagnostic	3
Dilated bile ducts	46
Pancreas mass	23
Enlarged gallbladder	6
Gallstones	2

Seven (13%) of these 53 patients had either normal study findings or findings that were not diagnostic of biliary obstruction. Forty of these 53 patients also underwent abdominal computed tomographic (CT) scanning, and in 36 patients, additional findings were noted as shown below.

Findings	No. of Patients
Pancreas mass	10
Pancreas mass (size only)	7
Pancreas mass (uncinate)	7
Nonpancreatic mass	1
Dilated bile ducts	4
Liver lesions	6
Splenomegaly	1

Ten patients had a mass noted that was not visualized on the US; seven patients had a mass of a different size noted on CT. In seven patients, the mass was noted to be arising from the uncinate process rather than the head of the pancreas. Four patients had bile duct dilatation not noted on the US and

six patients had liver defects noted that were felt to be suggestive of metastases. For the seven patients with nondiagnostic or normal US findings, the CT scan was normal in three patients and showed a pancreas mass in four patients and dilated bile ducts in two patients.

The Tc 99m liver-spleen scans were performed in 43 patients with the results shown below.

Findings	No. of Patients
Hepatomegaly	10
Splenomegaly	4
Dilated ducts	10
Liver defects	6
Diffuse liver disease	7
Normal	9

Six of nine US findings were abnormal. Biliary excretion scans were performed in 10 patients; the results of 2 studies were normal and 8 disclosed ductal obstruction. Arteriography was performed in 11 patients. Four patients were felt to have arteriographic evidence of unresectability. However, 2 of these patients subsequently underwent resections while 2 underwent bypasses. Seven patients disclosed no evidence of unresectability; 2 of these patients underwent resections while 5 underwent bypasses. One patient had an arterial anomaly noted, a right hepatic artery originating from the superior mesenteric artery, and this patient was found to harbor unresectable disease.

Forty-six patients had upper gastrointestinal (UGI) roentgenograms obtained. In the 16 patients with preoperative vomiting, 9 (56%) of 16 roentgenograms disclosed evidence of duodenal compression. In the 30 patients with no preoperative vomiting, only 6 (20%) of 30 UGI roentgenograms were abnormal.

Percutaneous transhepatic cholangiography (PTC) was performed in 31 patients with the results shown below.

Results	No. of Patients
Bile duct obstruction	31
No complications	21
Unsuccessful	2
Sepsis	7
Bleeding	1
Displaced catheter	3

Sepsis occurred in 7 (22%) of 31 patients. Major complications occurred in 8 (26%) of 31 patients. Bile duct obstruction was noted in all patients who underwent successful study; in 2 patients, no cholangiogram could be obtained. Twenty-one patients had no complications as a result of the procedure. However, major potentially life-threatening complications occurred in 8 patients. There was 1 case of bleeding severe enough to require transfusion, and 7 patients became septic, either from bile peritonitis or ascending cholangitis. Three patients experienced a dislodged catheter prior to operation.

Thirty-seven patients underwent endoscopic retrograde cholangiopancreatography (ERCP); in 7 patients, the ampulla could not be cannulated. Major complications occurred in 3 (10%) of 30 patients, consisting of two episodes of pancreatitis and one episode of ascending cholangitis.

Fifteen patients underwent both PTC and ERCP. In each PTC, an obstructed bile duct was noted. A dilated bile duct was similarly noted on nine of the ERCP studies, but in only one was an obstructed or narrowed pancreatic duct noted. Upper gastrointestinal endoscopy was performed as a separate procedure in four patients; no abnormal findings were found in each instance.

Twenty (24%) of 83 patients underwent resection; 17 Whipple procedures and 3 total pancreatectomies were performed. Two (10%) of these patients died during the postoperative period. Sixty-three patients underwent some form of biliary bypass procedure with 7 deaths (11%). For the 20 patients undergoing resection, the operative biopsy results were positive in 10 patients and negative in 8 patients; biopsy was not performed in 2 patients. The results of all operative biopsies are shown below.

Type of Biopsy	Positive Findings No. (%) of Patients
Wedge biopsy	
Tumor	13/17 (76)
Lymph node	17/22 (77)
Liver	14/20 (70)
Direct needle	
Tumor	13/16 (81)
Lymph node	4/7 (57)
Liver	2/4 (50)
Transduodenal	
Tumor	3/7 (43)

Wedge and direct needle biopsy specimens were taken from the primary tumor, regional lymph nodes, and the liver; each type of biopsy specimen was associated with a significant number of negative results. Only three (43%) of seven transduodenal tumor biopsy specimens disclosed carcinoma.

COMMENT

The patient with jaundice is usually considered to be harboring an obstruction because of a number of points in the medical history, physical examination, and laboratory screening tests. A history of abdominal pain, anorexia, or previous gallbladder surgery should alert the clinician, as should the presence of cholangitis or a palpable gallbladder. If the serum bilirubin level is greater than 171 μmol/L, or the alkaline phosphatase level is elevated out of proportion to the aspartate aminotransferase level or alanine aminotransferase level, this possibility is strengthened. An elevated serum amylase level or the recent onset of hyperglycemia may also be noted.[1] Others have looked at the predictive accuracy of the medical history, physical examination, and laboratory tests and noted that they were 80% to 85% accurate in indicating the presence of surgical jaundice.[2]

Many diverse recommendations exist in the literature regarding the management of patients with suspected obstructive jaundice. Some have felt that operative treatment must not be undertaken before determining the exact site and source of the obstruction.[2,3] Others have provided extensive algorithms for the systematic preoperative workup of patients once the presence of biliary obstruction is noted.[1-3]

In one published series,[4] however, the recommendation was made to operate after the initial US disclosed findings typical of a distal common bile duct obstruction, consisting of a dilated bile duct and dilated gallbladder without stones or a dilated bile duct with a small gallbladder containing stones. In this series, 61 of 61 patients with the former finding underwent a successful operation, whereas 19 of 19 patients with the latter finding had a successful outcome. We strongly concur with this approach, as we feel that nearly all of the information to be obtained from additional studies is an elaboration of the obvious. The experienced pancreatic surgeon can visualize, palpate, and mobilize structures during the operation to provide sufficient information to make a sound judgment regarding the feasibility of resection in nearly all cases of periampullary obstruction.

The reliance on US is, of course, to some degree dependent on the person performing and interpreting the study. Accuracy rates in the 80% to 90% range are to be expected for the demonstration of gallstones, dilated extrahepatic and intrahepatic ducts, and the presence of a pancreatic mass.[5,6] Common duct stones, on the other hand, are noted in less than one third of the patients.[5] This high accuracy rate, along with its

ready availability, low cost, and absence of side effects, makes the US the natural choice for the initial test in a patient with suspected obstructive jaundice.

Computed tomographic scanning is thought to be more accurate than US, is not compromised by obesity or excessive bowel gas, and can allow better definition of structures through the use of intravenous or oral contrast materials.[6] It has been used by some to diagnose unresectability,[7] but we disagree with this approach. In our study, CT scans disclosed additional data to the US in 36 of 40 patients. However, close examination of this information revealed that virtually every "additional" finding would have been noted by the surgeon during the operation. The Tc 99m liver-spleen scans likewise provided no additional information in this series and should not be performed. Biliary excretion scans have been recommended for special cases, but they only provide the same information suggested by liver function tests and abdominal US.[5]

Arteriography has been advocated preoperatively for a number of reasons, including documentation of unresectability or the demonstration of metastatic disease.[7] Others have found no clear pattern indicating unresectability.[8] We agree with this, as we were able to perform a resection in two of four patients felt to have angiographic criteria of unresectability. Likewise, only two of our seven patients with a normal arteriogram could undergo resection.

Perhaps the only legitimate reason to consider arteriography is to document the presence of major arterial anomalies, the most important of which is a hepatic artery originating from the superior mesenteric artery. Ligation of this vessel in a patient with jaundice will cause death in most cases,[8] but since the anomaly only occurs with a 15% incidence, and perhaps less than 25% of patients with pancreatic carcinoma can undergo resection, this anomaly will pose a problem in less than 5% of the patients overall. Even when present, the anomaly can usually be promptly recognized and the artery spared by an experienced surgeon.

Upper gastrointestinal roentgenograms have been recommended in an attempt to delineate those patients who may require gastrojejunostomy for impending gastric-outlet obstruction in addition to biliary bypass. It appears that the presence of preoperative vomiting is predictive; 9 (56%) of 16 patients in our series with vomiting had an abnormal UGI roentgenogram, whereas only 6 (20%) of 30 patients without vomiting had an abnormal study. We feel that the surgeon can adequately assess this at operation and would decry performing routine gastrojejunostomy because of the high associated stomal malfunction rate and the lack of proof of survival benefit.[9,10]

The two tests most likely to give definitive information are the PTC and ERCP. Unfortunately, these are also the two tests with the greatest potential for morbidity. The PTC may be successfully performed in over 90% of patients with a dilated ductal system. This figure, however, drops to about 70% in the presence of nondilated ducts.[5,11] Potentially life-threatening complications occur in 3% to 10% of patients, including peritonitis, ascending cholangitis, bleeding, drug reaction, and pneumothorax. A 0.2% to 0.9% death rate from this procedure has been described.[5]

The ERCP is successfully carried out in 80% to 90% of patients regardless of ductal dilatation, but it also carries a 2% to 7% major complication rate, including pancreatitis, sepsis, cholangitis, aspiration pneumonia, and instrumental perforation of the gastrointestinal tract. A procedure-related death rate of 0.1% to 0.2% has been described.[5,11] Seven (22%) of our 31 patients undergoing PTC developed postprocedure sepsis despite prophylactic antibiotic administration, leading us to view this procedure with considerable skepticism. One other patient developed serious bleeding from the liver, necessitating transfusion.

Our complication rate following ERCP was 10% (3/30), and is more typical of results found in the literature. We do not feel either of these procedures should be performed in the patient with obstructive jaundice and US evidence of distal bile duct obstruction. We agree, however, that under certain limited circumstances, their use should be considered (1) in the patient with a prior cholecystectomy and no evidence of a pancreatic mass for whom an ERCP and papillotomy may be therapeutic for a common bile duct stone; (2) if the clinical and laboratory evidence point to obstructive jaundice but dilated bile ducts are not noted on the US; (3) in a patient who has US evidence of proximal biliary obstruction (Klatskin tumor) for whom knowledge of the proximal and distal extent of the tumor is necessary in formulating both operative or nonoperative strategies; and (4) in the patient with distal bile duct obstruction, a pancreatic mass, and a strong history of alcohol ingestion who may have obstructive jaundice on the basis of chronic pancreatitis.

We would also not advocate preoperative biliary drainage by either PTC or endoscopically placed stents in view of the lack of definite proof of decreased operative morbidity from preoperative drainage and the potential morbidity from the stents.[12,13] Although we realize that most patients with pancreatic carcinoma are realistically incurable, the only chance for those very few patients with early tumors lies in resection. Also, we agree that operative bypass procedures provide better long-term palliation than stents and that operative bypass should be carried out in all low-risk patients who cannot undergo resection.[13]

We also do not favor preoperative percutaneous aspiration or biopsy. The possibility of misinterpreting the information from some patients with more favorable lesions (ie, bile duct or ampullary carcinoma, pancreatic cystadenocarcinoma, cystadenoma, and lymphoma) or assuming that all masses in the head of the pancreas are ductal carcinoma may occasionally deny patients a curative resection. Although diagnostic accuracy rates of up to 85% have been described,[14] these vary, and several cases of needle-tract dissemination from potentially curable lesions have been described.[11,15]

Limiting preoperative testing obviously puts a high premium on operative decision making. We agree with others that positive operative biopsies are not essential prior to embarking on pancreatic resection in the nonalcoholic patient with an obstructing pancreatic mass.[1,11] Although the operative biopsy is safe,[15,16] the possibility of false-negative results ranging from 6% to 14% in patients with pancreatic carcinoma makes reliance on a biopsy alone uncertain.[15,17]

On the basis of our findings, we feel that the experienced surgeon can correlate the patient's history, laboratory tests, US results, and operative findings with a high degree of accuracy to provide patients with obstructive jaundice a cost-efficient and safe diagnostic workup and an operation that is designed to provide resection for all patients who may benefit from it and bypasses for all others. In the preoperative workup of these patients, less is indeed better.

Discussion

L. BEATY PEMBERTON, MD, Kansas City, Mo: This report asks a very important question: How many tests do we need to perform before we operate on a patient with jaundice? I thank the authors because they have documented my bias when I have a choice in my practice. This report shows that US, CT, biliary excretion scans, PTC, and ERCP are all different ways of showing that the common bile duct is obstructed. In my mind, this series of tests has always presented an unnecessary duplication.

Did you think the UGI roentgenogram helped you in any way to decide about the degree of duodenal obstruction and, therefore, the need for a gastrojejunostomy in either the patients who vomited or the six who did not vomit but had a positive UGI roentgenogram? If you always perform a gastrojejunostomy as part of the bypass operation for obstructive jaundice, then you probably don't need to know whether the duodenum is obstructed. However, if you base the operative decision on the amount of duodenal obstruction or the symptoms that this stenosis produces, as I usually do, then adding the UGI roentgenogram would be helpful. I would appreciate the authors' comments on this aspect of their report.

CARLOS A. PELLEGRINI, MD, San Francisco, Calif: The development of many new techniques to study the biliary tract and pancreas over the last two decades has allowed us to diagnose lesions in these areas with unprecedented accuracy. As was correctly pointed out by the authors, many physicians have the idea that every patient suspected of harboring a neoplastic process in the biliopancreatic area should be subjected to many or all of these tests. This concept is wrong and has led to unnecessary costs, suffering, and confusion in the diagnosis of the lesion. However, swinging the pendulum all the way to the other side is not the right answer, either.

After obtaining a good history, physical examination, and basic liver function test results, the clinician should carefully select the tests that are appropriate. In most cases, US will be the choice as it can accurately determine the level of obstruction and the presence of cholelithiasis. If, based on the medical history and the level of serum bilirubin, we believe that the patient has a neoplastic obstruction, we choose a CT scan as it more accurately delineates masses in the head of the pancreas and distant metastasis.

At this stage of the workup, if there is a mass confined to the head of the pancreas with no dilatation of the extrahepatic biliary tract, we believe the average patient needs no further workup and should undergo exploration, provided this is done by a team ready to carry out a duodenopancreatic resection if indicated. It is important to underscore, however, that if there is no obvious mass on the CT scan, or if there is doubt regarding the origin of the pancreatic lesion, ERCP is the test of choice.

Transhepatic cholangiography plays no role in this situation, but it provides invaluable information in high lesions of the bile duct (ie, Klatskin tumor). We do not advocate percutaneous fine-needle aspiration since this can be done expeditiously in the operating room. Instead, we reserve this procedure for those patients who are not candidates for an operation and for those suspected of having lymphoma as this lesion can be effectively treated nonoperatively. We have abandoned routine preoperative angiography in patients with pancreatic masses.

While I agree that less is better, I also believe one must use the plethora of information available today with regard to the accuracy and clinical value of each test in each diagnostic situation. Intelligent selection rather than indiscriminate cutting is the key to this problem.

A. RAHAM MOOSSA, MD, San Diego, Calif: The authors have exaggerated their data to make a very important point, ie, that we do not need to perform all the available tests in every patient with jaundice. Let me look at the report in perspective. The title is a bit misleading. The authors talk about patients with obstructive jaundice, but they have only selected and analyzed retrospectively those patients who turned out to have periampullary cancer. There are many other causes of obstructive jaundice other than periampullary cancer and we often have to differentiate between them preoperatively.

The second point is that US does not delineate the distal third of the common duct in about one third of all cases. So, while I agree with the authors that US is the first line of investigation and that many patients can have an operation without any further tests, I do not agree with their thesis that all the other tests are not helpful. My own bias is that the UGI series and radionuclide scans are totally useless and should not be used in the evaluation of the jaundiced patient today.

However, some patients in whom the cause of the jaundice is not clear may need to have one or more ancillary investigations, such as the CT scan, PTC, ERCP, and/or angiography. These may, in selected patients, help the surgeon plan an operative strategy and indicate to the patient what he or she is likely to do. I agree with Dr Pellegrini that we should not swing totally to the other end. Medicolegally, though, we must remember that we have to provide the patient with some information that enables us to obtain informed consent.

One other important point about this report is the fact that the surgeons are very experienced. They are certainly more experienced than the average surgeon in an average community setting. Hence, they can "get away with a lot." I would hate to have young surgeons walking out of here exploring patients with jaundice solely on the basis of liver function test results and US.

In some patients, especially those who have had previous operations where the diagnosis is uncertain, when there may be anticipated technical problems associated with an earlier exploration, or when the surgeon anticipates other time-consuming maneuvers on the operating table, the surgeon is wiser to use some, not all, of these invasive preoperative measures to arm himself or herself with additional information. This is very important because a large number of medicolegal problems arise from just that issue. The surgeon should not do a laparotomy for jaundice without any plan, without knowing what he or she is likely to do, and without discussing options with the patient and, if at all possible, with the relatives.

STUART M. POTICHA, MD, Chicago, Ill: I agree with the authors' premise and wonder if they would consider adding a needle aspiration cytology to their US. While a negative diagnosis would not prevent exploration and in some cases would not prevent resection, most surgeons would prefer to have a positive diagnosis. I would certainly prefer to have the pathologist discuss whether it is positive or negative the night before surgery rather than when the patient is on the operating table.

FRANK T. JORDAN, MD, Las Vegas, Nev: I agree basically with the premise that less is better. Dr Pickleman, how does your group handle the one third of these patients with obstructive jaundice on the basis of malignancy who end up with outlet obstruction of the stomach? Do you handle it solely by medical history? Do you perform a bypass for all of the patients knowing that if you don't do so at the initial operation and they come back with obstructive jaundice they will be a much sicker group?

Is there any role for the CT scan showing metastatic disease in the liver or lymph nodes? Would you exclude that group of patients from operation with or without biopsy proof of metastatic disease? Other authors have written that they just send patients for radiation therapy and chemotherapy. I don't agree with that philosophy, but what are your thoughts?

DR PICKLEMAN: I actually thought this report would bring the

crazies out of the walls, but I am heartened by your comments.

Dr Pemberton asked whether a preoperative UGI roentgenogram helps. Our opinion is that it probably does not. If you have a patient who vomits preoperatively and cannot undergo resection, gastric bypass in addition to the biliary bypass is clearly needed. If that patient is not vomiting preoperatively and does not appear to have any duodenal impingement, I don't think there is any role for a gastrointestinal bypass.

Dr Pellegrini commented on the additional information provided by CT. I am not sure we share that viewpoint for most patients. By mobilizing the pancreas, you can determine whether the uncinate process is involved. I don't think ERCP is necessary in too many patients. Remember the way these patients came to our attention in the first place; they had jaundice and we had a US that showed they had obstructive jaundice. These patients were going to require some procedure. Are we going to quibble about whether it is an operative or an endoscopic procedure, perhaps?

Dr Moossa questioned whether the US may provide incomplete information, and it does in some cases. In those cases, we would not argue against doing CT or even proceeding to more invasive studies. What we are talking about in this report is the routine patient who presents with obstructive jaundice, a mass in the pancreas, or a dilated bile duct in a patient who does not have a history of alcohol ingestion.

Dr Poticha, we are not very sanguine about the preoperative role of needle aspiration. Misdiagnoses are common and several cases have been reported in which cancer was disseminated along the needle tract.

Editorial Comment

This is a provocative report from an experienced group of surgeons, advocating much less preoperative testing than is currently performed in most patients with obstructive jaundice. I am not sure that the authors adequately support their argument with the data presented, since a number of patients had normal study results and, therefore, might have been difficult to diagnose as having "obstructive" jaundice.

Certainly, it is a common experience for surgeons to see a patient hospitalized on a medical service for 7 to 10 days, having multiple repetitive diagnostic studies, when the diagnosis seems obvious on the basis of initial studies. I agree with the authors that a US examination should be a basic study in all patients. I also agree that many patients are overstudied. However, there is a place for ERCP if one suspects a periampullary cancer since it can be seen and a biopsy can be perfomed in some instances. Liver-spleen scans, arteriography, and UGI roentgenograms provide little information that cannot be found by the operating surgeon.

This report should stimulate thought and discussion among surgeons and other physicians interested in biliary and pancreatic disease.

Cleveland, Ohio

Function of Pancreas Allografts More Than 1 Year Following Transplantation

Francis H. Wright, MD; John L. Smith, MD; Scott A. Ames, MD; Barbara Schanbacher, RN; Robert J. Corry, MD

• At the University of Iowa, Iowa City, 75 pancreas transplant procedures were performed for type I diabetes mellitus from March 1984 to September 1988. Forty-seven of these transplants were performed simultaneously with kidney transplants from the same donor; 23 followed previous kidney transplants, and 5 were preuremic pancreas-only transplants. The 1-year patient survival rate is 85% and pancreas graft survival rate is 54%. The simultaneous kidney and pancreas group had a 1-year patient survival rate of 82%, a pancreas graft survival rate of 59%, and a renal graft survival rate of 73%. Thirty-one of 70 kidney and pancreas recipients had a functioning pancreas 1 year post transplantation and 26 of 31 currently have a functioning pancreas and are insulin free. Patient symptoms of neuropathy and gastroenteropathy are improved with long-term graft function. Some patients may develop type II diabetes post transplantation with impaired glucose tolerance despite high insulin production by the graft. Pancreas transplantation is the only therapy that achieves a euglycemic state as indicated by glycosylated hemoglobin and glucose tolerance testing. Centers must continue to follow up patients on a long-term basis to determine the final effects on the secondary complications of diabetes.

***(Arch Surg.* 1989;124:796-800)**

Diabetes mellitus is a major health problem affecting over 5 million people in the United States, with some 10 000 new cases diagnosed annually. The disease has a marked impact on both the duration and quality of life: it is the major cause of blindness in adults; myocardial infarction is 2 to 3 times more common in diabetics; peripheral vascular disease leads to amputation in 10% of diabetics; and renal failure occurs with increased frequency. The life expectancy of diabetics is reduced by one third, compared with the general population. It is this severe morbidity and premature mortality that has driven the development of pancreatic transplantation as an attempt to reverse or slow the progression of the secondary complications of diabetes by reestablishing a normal state of glucose metabolism.

Accepted for publication March 6, 1989.

From the Department of Surgery, University of Iowa College of Medicine and Transplantation Services, University of Iowa Hospitals and Clinics, Iowa City. Dr Wright is now with Parkview Medical Center, Nashville, Tenn.

Read before the 96th Annual Meeting of the Western Surgical Association, San Diego, Calif, November 14, 1988.

Reprint requests to Parkview Medical Center, 250 25th Ave N, Room 207, Nashville, TN 37203 (Dr Wright).

The first clinical pancreas transplantation was performed by Kelly and Lillehei et al[1] at the University of Minnesota, Minneapolis, in December 1966. During the next decade, approximately 60 pancreas transplant procedures were performed, with only 2 grafts reported functioning for more than 1 year. The refinement of surgical techniques and better immunosuppressive strategies have led to improved results and a consequent increase in cases. Over 1200 pancreas transplant procedures have been performed worldwide.[2] The number of patients available for long-term follow-up remains small and many of these patients underwent transplantation with significant preexisting diabetic complications. Therefore, we have yet to completely answer the question of what are the beneficial effects of pancreas transplantations. The purpose of this report is to describe the course of patients who have remained free of insulin-replacement therapy with a pancreatic graft functioning for more than 1 year.

MATERIALS AND METHODS

In the University of Iowa transplantation program 75 pancreas transplants were performed from March 1984 to September 1988. Sixty-eight were primary transplants and 7 were retransplants. Forty-seven pancreas transplants were performed simultaneously with kidney transplants from the same donor, 23 were performed following successful kidney transplants from different donors, and 5 were performed in preuremic diabetic recipients. The 5 preuremic recipients will not be addressed further in this report. All were whole-organ pancreaticoduodenal transplants with a short duodenal segment. Pancreatic exocrine drainage was by duodenojejunostomy in 32 cases and by duodenocystostomy in 43 cases.

Surgical Techniques

The surgical techniques employed at the University of Iowa for the donor and recipient have been described in detail previously.[3,4] In brief, the pancreas is placed in the iliac fossa analogous to a kidney transplant, with the donor portal vein anastomosed end to side to the recipient external iliac vein and with a donor aortic patch including the celiac axis and superior mesenteric artery origins anastomosed end to side to the external iliac artery. Technical variations used when removing a liver from the same donor have been described.[5,6]

Following revascularization of the pancreas, a donor splenectomy is performed. Exocrine drainage in the early part of the series was by side-to-side duodenojejunostomy without a Roux-en-Y limb. Duodenocystostomy, using a short duodenal segment, was developed later and is now the procedure of choice for exocrine drainage.[7] In the

Fig 3.—Patient, renal graft, and pancreas graft survival for 47 simultaneous pancreas and kidney transplants.

Fig 2.—Overall patient and pancreas graft survival in 70 cases, including 47 simultaneous kidney and pancreas transplants and 23 pancreas-after-kidney transplants.

Fig 4.—Patient and pancreas graft survival in 23 pancreas-after-kidney transplants.

simultaneous renal and pancreas recipient, the kidney is placed in the opposite iliac fossa in the standard manner. The simultaneous transplantation can be performed through a midline abdominal incision or bilateral iliac incisions, as is our preference.

Immunosuppression

Immunosuppression has included induction with cyclosporine, azathioprine, steroids, and Minnesota antilymphocyte globulin in most cases, as described by Sollinger et al.[8] Maintenance immunosuppression has included cyclosporine, azathioprine, and prednisone. Rejection episodes were treated with steroid bolus therapy with OKT3 or Minnesota antilymphocyte globulin used for steroid-resistant rejection.

Patient Management

Recipient follow-up studies have included routine screening of blood chemistries and urine and serum amylase levels; periodic determination of glycosylated hemoglobin levels (HbA_{1C}); oral glucose tolerance tests with insulin and C-peptide determinations; and periodic graft imaging with radionuclide scanning and, more recently, with magnetic resonance imaging.[9] Patients have also been surveyed to assess the quality of life and symptomatic improvement of neuropathy, retinopathy, gastroenteropathy, and overall well-being, as evidenced by symptoms of fatigue or depression.

RESULTS

Of the 70 total pancreas recipients considered in this report, 31 were free of insulin replacement and had normal glucose metabolism at 1 year. Actuarial survival data for this group of patients is shown in Fig 1. Twenty-six (84%) of 31 recipients continue to have satisfactory pancreatic function at a mean of 34 months after transplantation (range, 13 to 54 months). This group includes 11 bowel-drained grafts and 15 bladder-drained grafts. Of the 5 instances of late pancreas graft loss, 3 were lost to chronic rejection, 1 was lost to a late episode of acute rejection, and 1 graft loss was due to death from myocardial infarction in a patient with a functioning pancreas graft 3½ years post transplantation who had returned to dialysis and was not a candidate for renal retransplantation.

The 1-year patient survival rate for the entire series is 85% and the pancreas graft survival rate is 54% (Fig 2). Actuarial survival data for the simultaneous kidney and pancreas recipients show 1-year patient survival rate of 82%, renal graft survival rate of 73%, and pancreas graft survival rate of 59% (Fig 3). For those receiving a pancreas transplant after a kidney transplant, patient survival at 1 year is 91% with a pancreas graft survival of 41% (Fig 4).

Metabolic Control of Diabetes After 1 Year

This group of patients demonstrates that a functioning pancreas transplant is capable of restoring normal glucose metabolism, as indicated by glycosylated hemoglobin levels. The mean HbA_{1C} level in patients receiving insulin therapy before transplantation was 7.91% (±0.51%); the mean long-

Fig 5.—Top, Oral glucose tolerance tests in 26 cases more than 1 year after pancreas transplantation. Bottom, Serum insulin levels obtained during glucose tolerance testing. Note that the cases showing impaired glucose tolerance also show higher serum insulin levels. Oral hypoglycemics further raise insulin levels but improve glucose tolerance.

term hemoglobin level after pancreas transplantation was 5.42% (±0.32%), which was a significant reduction ($P = .0007$). In contrast, a group of diabetic kidney recipients who were not candidates for pancreas transplantation had a mean HbA_{1C} level of 7.54% (±0.69%) despite close medical follow-up and blood glucose monitoring at home.

Periodic oral glucose tolerance tests with serum insulin and C-peptide determinations have shown two patterns in patients with long-term function. The first pattern is that of normal glucose tolerance and insulin response (Fig 5). The second pattern is that of abnormal glucose tolerance associated with normal or increased insulin production by the graft (Fig 5). This appears analogous to the development of type II diabetes, which we have described in detail elsewhere.[10] Those patients appear to benefit from oral hypoglycemics and a reduction in maintenance steroid doses that lead to improved glucose tolerance (Fig 5). Other patients with this abnormal pattern have required exogenous insulin replacement and their grafts have been classified as failed. However, these patients continue to have blood flow to the transplanted pancreas on radionuclide scanning and to maintain graft parenchyma on magnetic resonance imaging, unlike those grafts that have undergone chronic rejection and show decreased blood flow and graft size.

Complications

Late complications requiring hospitalization after more than 1 year of graft function have occurred in 13 (50%) of 26 patients. These patients are listed in the Table. None of these late complications resulted in graft loss or death.

Two patients developed failure of their renal transplants and underwent successful retransplantation with another kidney. One of these patients has received a third renal transplant and continues to have completely normal pancreatic and renal graft function, despite loss of the first two kidney transplants.

Thirteen Patients and Their Complications Occurring More Than 1 Year Following Successful Pancreas Transplantation

1. Recurrent gastrointestinal bleeding; recurrent lymphocele requiring ultrasound-guided percutaneous aspiration
2. Femoropopliteal bypass for peripheral vascular disease; ray amputation of toe with healing
3. Transplant pyelonephritis
4. Toe amputation
5. Bleeding from duodenal segment requiring revision of duodenocystostomy from segment to button
6. Incisional hernia repair and postoperative graft pancreatitis; midfoot amputation with healing
7. Late perforation of duodenocystostomy requiring surgical closure, related to neurogenic bladder dysfunction
8. Late perforation of duodenocystostomy requiring surgical closure, related to cystoscopic instrumentation
9. Graft pancreatitis related to neurogenic bladder and urinary retention, requiring hospitalization and Foley catheter drainage
10. Graft pancreatitis related to neurogenic bladder and urinary retention, requiring surgical exploration and catheter drainage
11. Stroke with residual hemiparesis and aphasia
12. Cholecystectomy for chronic cholecystitis and cholelithiasis
13. Erosion of inflatable penile prosthesis into urethra with urethroscrotal fistula, requiring removal of prosthesis and catheter drainage

Subjective Evaluation of Patients

Patients were surveyed to assess symptomatic improvement of neuropathy, retinopathy, gastroenteropathy, and fatigue and/or depression. Twenty-five of 26 patients were available for the survey. Results showed that 22 (88%) of 25 patients had visual problems at the time of the transplantation and 16 (73%) of 22 noted stabilization or improvement in their vision. Sixteen (64%) of 25 had symptoms of neuropathy before transplantation and 13 (81%) of 16 noted subjective improvement. Twenty (80%) of 25 had symptoms of gastroenteropathy prior to transplantation and 14 (70%) of 20 noted stabilization or improvement in symptoms. Twenty (80%) of 25 had symptoms of fatigue or depression affecting their sense of well-being prior to transplantation and 13 (65%) of 20 noted symptomatic improvement.

COMMENT

Our group of successful pancreas transplant recipients provides additional data showing that these organs may function for a long period and maintain normal glucose metabolism as indicated by glycosylated hemoglobin and glucose tolerance testing. Pancreas transplantation is the only therapy that can achieve this euglycemic condition in a diabetic patient. Patients who reach the 1-year mark with satisfactory graft function have a low mortality and minimal rate of pancreas graft loss thereafter. Many patients also demonstrate subjective symptomatic improvement or stabilization of neuropathy and gastroenteropathy. The quality of life and general well-being are improved.

Complications occur in a significant number of cases, even after long-term pancreatic function is established. Many of these are related to preexisting secondary complications of diabetes, such as peripheral vascular disease and neurogenic bladder dysfunction, which were present at an advanced stage at the time of transplantation. Preexisting bladder dysfunction may be an indication for enteric exocrine drainage. Our experience has shown that these late complications can be treated successfully without graft loss or death, but earlier transplantation prior to well-established diabetic com-

plications should result in fewer long-term problems.

Also of concern is the late development of type II diabetes, in which the pancreas graft produces normal or high insulin levels and appears normal on imaging studies, but in which the recipient has abnormal glucose tolerance. We have shown that this condition can be improved by oral hypoglycemic agents and a reduction of steroids. The incidence of this condition is similar to that of steroid-induced diabetes in renal transplant patients. Cyclosporine has also been shown to affect pancreatic β-cell function[11] and to be associated with glucose intolerance in renal transplant recipients.[12] The development of new immunosuppressive agents and strategies that avoid steroid use may be of particular significance for pancreas transplantation in the future.

Insulin independence and normal glucose metabolism, while no small accomplishments, are not the only long-term goals of pancreas transplantation. The prevention of secondary complications is difficult to assess, but evidence from a number of transplantation centers suggests progress. Neuropathy has been shown to improve following pancreas and renal transplantation.[13] Improved peripheral blood flow and tissue oxygenation has been reported.[14] Diabetic nephropathy may be ameliorated in transplanted kidneys[15] or in native kidneys of pancreas-only recipients.[16] Retinopathy, once established, appears to be the most refractory complication.[17]

The price of pancreas transplantation has been the risk of the operation and of immunosuppression. Surgical risks have been reduced[18] and the majority of pancreas transplants have been performed in patients committed to immunosuppression for renal transplantation. We believe that pancreas transplantation should be considered in all suitable patients with diabetic renal failure. Data show that pancreas transplantation does not increase patient mortality or renal graft loss.[19]

A simultaneous renal and pancreas transplant procedure offers the best success rate because the ability to monitor kidney function assures early diagnosis and treatment of rejection. The simultaneous procedure should be performed at an early stage in the development of diabetic nephropathy prior to the requirement for dialysis and at an earlier stage of secondary complications. Pancreas transplantation after renal transplantation may be done, but with the understanding that all centers have reported lower pancreas graft survival rates; renal graft survival remains unchanged.[20]

While renal transplantation provides a clear benefit to the diabetic, patients who receive only a pancreas transplant are subjected to the risks of surgery and immunosuppression for less well-defined benefits. Pancreas transplantation in the preuremic diabetic should continue to be viewed as investigative and should remain confined to research centers that have particular expertise.

There are many reasons for optimism about pancreas transplantation. Early mortality and graft loss rates have improved. The development of urinary exocrine drainage with urinary amylase determination provides a better means of monitoring graft rejection, allowing earlier diagnosis and treatment.[21] Improved preservation techniques[22] allow a less urgent approach to surgery and may lead to sharing of organs for improved histocompatibility matching.[23]

It is expected that results will continue to improve and that evidence will continue to accumulate showing a positive effect on the secondary complications of diabetes. Pancreas transplantation will then become available to a larger number of patients and will take its place in the routine armamentarium of the surgeon who performs transplantations.

We thank Louise McNutt for providing statistical analysis and Lana Slagle for her word processing assistance.

Discussion

FOKERT O. BELZER, MD, Madison, Wis: I would like to expand on some of the things Dr Corry mentioned and remind the audience that, until recently, pancreatic transplantation was the most experimental of all transplants with actually the worst results. It is also important to remind the audience that the techniques for kidney, liver, and heart tranplantations were actually worked out 10 to 20 years ago, while the major advances in pancreas transplantations have occurred in the last 5 years. Several of these advances were made by the Iowa group.

Until 4 years ago, the main graft used in most institutions was the

segmental graft (ie, the tail of the pancreas) and because of the precarious blood supply, postoperative thrombosis occurred frequently. Many of these grafts had to be removed shortly after transplantation. Most of us have now gone over to use the whole pancreas transplant, except in Europe, where they still use segmental grafts.

We initially used a duodenal button which is actually the ampulla. As you can see from these 12 patients, excellent patient pancreas and kidney survival was obtained. With the modification of using a duodenal segment, even better graft survival was obtained with a patient survival rate of 100% and kidney and pancreas survival rate of 96%. Notice, however, that the follow-up course is shorter than with the duodenal button.

I concur with Dr Corry that pacreatic transplantation now is a safe and effective procedure. The discussion about who should get the organ, the liver or the pancreas, has been solved because in Iowa and Wisconsin we now routinely take both organs, separate them, and give them to two different patients.

In this report, Dr Corry mentioned improvements in eyesight and visceral enteropathy. Just a word of caution—many of our diabetic patients actually improve their visceral enteropathy and stabilize their eyesight with just a kidney transplant alone. As far as their vascular disease is concerned, it is difficult to expect that the pancreas transplant will reverse preexisting vascular disease. My question to Dr Corry is, what is the future of pancreas transplantation at a much earlier stage—for patients who have not developed the ravages of end-stage diabetes? Should we be performing transplantations before patients have renal failure and other diabetic complications?

A. Rahim Moossa, MD, San Diego, Calif: Diabetics in end-stage renal failure are high-risk patients for any major operation. Hence, the mortality and morbidity have been high. Looking at the report, I find the mortality for simultaneous kidney and pancreas transplantations is about 18%. The mortality for the sequential transplantation is about half (10%), and yet, I get the impression that Dr Corry advocates simultaneous transplantations in spite of the much higher mortality. Perhaps he could explain that to us.

My second question is about the assessment of β-cell function. Dr Corry has used the oral glucose tolerance test. I think this is a very misleading and not very accurate way of measuring β-cell function. Maybe he could explain to us why he didn't use the intravenous glucose tolerance test or the glucagon tolerance test.

All the patients who have had a transplant have a high basal insulin because the insulin is secreted into the systemic circulation. So the high basal insulin doesn't mean anything. If we are going to call patients type II diabetics, we can only do so after doing glucose studies demonstrating, therefore, resistance to insulin and demonstrating the lack of suppression of hepatic glucose output. Maybe he would explain that as well to us.

Therefore, I believe the insulin profile itself doesn't mean anything. The oral glucose tolerance does not really discriminate. Finally, he uses cyclosporine in all patients. We know from animal studies that cyclosporine damages the β cell. Has he found this of any clinical relevance in the long-term follow-up of the patients?

Dr Corry: I would like to congratulate Dr Belzer on the outstanding results that he showed from the University of Wisconsin. The question of whether this procedure can be performed in the preuremic is very difficult to answer. It will have to await the immunosuppressive strategies because unless the patients have a complication, it will be a problem to give them immunosuppressive drugs. This probably should be done in only a few centers such as your own and ours and possibly Minnesota where a large series is being performed.

Dr Moossa, the survival of the combined operation is not as good, but you will remember the slide I showed where we began preselecting the patients and eliminating patients who have cardiovascular disease. The survival can be improved in that particular way, but I think you are right. A very careful selection policy has to be adopted. We can't be rendering a higher mortality to these patients than they otherwise would have while receiving insulin therapy. The enthusiasm of these centers 4 and 5 years ago in selecting patients improperly led to a higher initial mortality.

Most of the programs now have a much more acceptable mortality. In the last 2 years, only one patient has died in our program. This can be monitored by appropriate selection.

You are right. The intravenous glucose tolerance test is much more sensitive and we have used it occasionally. I am sure that makes a major difference if you are monitoring the HbA_{1c}s very precisely. Certainly these patients are all free of insulin and have normal carbohydrate metabolism. The cholesterol levels are dropping off, and no matter how you monitor it, there is a definite response to either intravenous or oral glucose.

The high basal insulin levels worried us, too, in response to the systemic delivery. Obviously, the insulin levels are going to be higher, the response is going to be higher, and we are still concerned about the problem that was mentioned yesterday of whether the first pass of insulin should be through the liver. We are working out techniques now of joining the portal vein to the superior mesenteric vein by reversing the flow (ie, putting the splenic vein into the superior mesenteric vein so the first pass would be through the liver); I am not sure this is going to work out technically. The other option is to put the pancreas behind the stomach, a much more difficult operation technically, and join the portal vein to the spelenic vein.

I think the type II diabetes may be a misnomer. They may be steroid-induced diabetics or cyclosporine-induced perhaps. I think it does damage β cells. It is the only drug we have right now. It also damages the kidney and other solid organs. We may have to await better immunosuppressive drugs before this is applied to preuremic patients.

Changes in Tibial Venous Blood Flow in the Evolving Compartment Syndrome

William G. Jones II, MD; Malcolm O. Perry, MD; Harry L. Bush, Jr, MD

• A sustained increase in muscle compartment pressures can cause tissue necrosis. When compartment pressures exceed recumbent tibial vein pressures, blood flow in tibial veins may be impaired. These changes can be detected by Doppler venous flow evaluation. In 26 patients at risk for compartment syndrome, serial examinations, Doppler venous flow, and measurements of compartment pressures were performed. All patients with abnormal Doppler venous flow results had or developed neuromuscular deficits. Patients with normal Doppler venous flow either initially or after fasciotomy did not develop the compartment syndrome. This syndrome can be evaluated and followed up sequentially by measuring Doppler venous flow in tibial veins.
(*Arch Surg*. 1989;124:801-804)

Compartment syndromes result from increased pressure within a limited space that compromises the circulation, viability, and function of the tissue within that space.[1] Compartment syndromes in the lower extremity arise after a variety of insults, including bleeding, postischemic swelling, fractures, soft-tissue trauma, excessive muscular stress, and after closure of fascial defects.[2-6] These insults initiate a series of changes leading to a common end point where the volume of tissue within the fixed space of an extremity compartment is increased. Unrelieved, a progressive or sustained increase in compartment pressure can lead to neuromuscular necrosis and permanent disability.

Compartment syndromes may be successfully treated by surgical decompression if the diagnosis is established before the onset of irreversible tissue ischemia.[7] Various methods have been employed in the evaluation of extremities at risk, including physical examination,[1] direct measurement of compartmental pressures,[8,9] and nerve conduction velocity studies.[10] However, none of these methods has proved completely reliable and satisfactory.

In the lower extremity, when compartment pressures exceed recumbent tibial vein pressures, tibial venous flow may be impaired. Such changes in tibial venous flow can be detected by transcutaneous Doppler venous flow (DVF) evaluation. This study was undertaken to determine the usefulness of DVF study in the evaluation of patients at risk for development of compartment syndromes.

PATIENTS AND METHODS

During a 12-month period, all patients deemed at risk for lower-extremity compartment syndromes by the Vascular Surgical Service at The New York Hospital–Cornell University Medical Center, New York, NY, were studied. Suspicion of possible compartment syndromes was based on a clinical history of insult consistent with the diagnosis, as well as the findings of swelling, edema, and noncompliant anterior compartments on physical examination. Serial clinical and laboratory examinations, DVF studies, and measurements of compartment pressures were performed on all patients.

All examinations and studies were performed initially and serially at intervals of every 2 to 6 hours, depending on the clinical situation. The presence of sensory and motor deficits, tenderness, or ischemia was noted on each examination, in addition to determinations of white blood cell count, serum potassium, and creatine phosphokinase (CPK), and the presence of urinary myoglobin.

Doppler studies were performed at the patient's bedside using a handheld instrument (Model 811, Parks Medical Electronics, Aloha, Ore) and ultrasonic gel (Aquasonic 100, Parker Laboratories, Orange, NJ). Phasic and augmented venous flow were assessed, as well as the presence of respiratory variation. Doppler studies were divided into three groups: normal phasic flow, loss of phasic flow, and loss of both augmented and phasic flow.

Direct measurements of compartment pressures were obtained in all patients using either the solid-state transducer intracompartmental catheter (STIC, Model 295-1, Stryker Surgical Corp, Kalamazoo, Mich) or the infusion method as described by Whitesides et al.[8] After sterile preparation of the skin with 10% povidone-iodine solution and calibration of the device, the catheter was inserted into the anterior compartment and the compartmental pressure was determined. Two to three readings through separate insertion sites were obtained for each measurement to ensure accuracy. Compartment pressures of greater than 30 mm Hg were considered abnormal.

Indications for surgical decompression initially included the presence of abnormal neurologic findings or compartment pressures greater than 30 mm Hg. As our experience and confidence with DVF studies progressed, indications for operation were expanded to include loss of DVF signals in the appropriate clinical setting. Decompression was accomplished using the technique of fasciotomy as described by Patman.[11]

RESULTS

Twenty-six patients at risk for lower-extremity compartment syndromes were studied over a 12-month period, with ages ranging from 16 to 81 years. Etiologic characteristics of insults leading to signs of compartment syndrome are listed in the following tabulation:

Characteristics	No. of Patients
Postembolectomy	8
Arterial thrombosis associated with intra-aortic balloon pulsation device	5
Superficial femoral artery injury	3
Extremity bleeding after anticoagulation	3
Thrombosis after percutaneous transluminal angioplasty	2
Popliteal artery aneurysm thrombosis	2
Other causes of arterial thrombosis	1
Closed fracture	1
Soft-tissue injury	1

Clinical data from 15 patients are listed in Table 1.

Accepted for publication February 28, 1989.

From the Division of Vascular Surgery, Department of Surgery, The New York Hospital–Cornell University Medical Center, New York, NY (Drs Jones and Bush); and Vanderbilt University Medical Center, Nashville, Tenn (Dr Perry).

Read before the 96th Annual Meeting of the Western Surgical Association, San Diego, Calif, November 15, 1988.

Reprint requests to Division of Vascular Surgery, Vanderbilt University Medical Center, Nashville, TN 37232 (Dr Perry).

Table 1.—Clinical Data in 15 Patients With Suspected Lower-Extremity Compartment Syndromes*

Patient/Age, y/Sex	Diagnosis	Initial Neurologic Examination Findings	DVF Findings	CP, mm Hg	Outcome
1/29/M	Lower-extremity bleeding	Normal	Normal	14-21	Recovery
2/37/M	Lower-extremity bleeding	Normal	Normal	8-12	Recovery
3/67/F	Postembolectomy	Normal	Normal	9-12	Recovery
4/65/F	Postthrombectomy	Normal	Normal	16-22	Recovery
5/79/F	Postthrombectomy	Normal	Normal	20-24	Recovery
6/16/M	Tibial fracture	Normal	Normal	18-23	Recovery
7/72/M	Postthrombectomy	Normal	Normal	10-18	Recovery
8/69/M	Lower-extremity bleeding	Normal	Normal	14-19	Recovery
9/21/M	Crush injury	Normal	Normal	16-19	Recovery
10/81/F	Postthrombectomy†	...	+	19-24	Foot drop‡
11/66/M	Possible embolism	Abnormal	–	34	Foot drop‡
12/68/M	Thrombosis	Normal	+	28-36	Foot drop‡
13/59/M	Postthrombectomy	Normal	+	22-30	Necrotic muscle at fasciotomy
14/66/M	Thrombosis	Normal	Normal	28-30	Recovery
15/79/F	Postembolectomy†	...	Normal	29-35	Recovery

*DVF indicates tibial Doppler venous flow; CP, compartment pressure; normal, normal phasic and augmented flow with respiratory variation; plus sign, loss of phasic flow—augmented flow present; and minus sign, loss of phasic and augmented flow.
†Patient was comatose on examination.
‡Fasciotomy was refused.
§No evidence of compartment tissue damage was noted at examination.

Table 2.—Summary of Results of Neurologic Examination, CP, and DVF in 26 Patients at Risk for Compartment Syndromes*

	No. of Patients	Abnormal Initial Neurologic Examination Findings	Permanent Deficit
Abnormal DVF/abnormal CP	7	5	3†
Abnormal DVF/normal CP	2	0‡	2§
Normal DVF/abnormal CP	2	0‡	0
Normal DVF/normal CP	15	0	0

*CP indicates compartment pressure; DVF, tibial Doppler venous flow.
†Includes two patients who refused fasciotomy and one patient with necrotic muscle found at examination.
‡One patient was comatose at examination.
§Includes one patient who refused fasciotomy and one patient with necrotic muscle found at examination.

A summary of the results of neurologic examinations, DVF, and compartment pressures are shown in Table 2. Nine of 26 patients had abnormal DVF, and 7 of these had high compartment pressures; changes in DVF preceded changes in compartment pressures in 4 patients. All patients with abnormal DVF had or developed neuromuscular dysfunction, including presence of peroneal nerve symptoms, decreased sensation in the interdigital cleft, and painful foot extension. Two patients had normal DVF and high compartment pressures (35 and 40 mm Hg) but did not develop neuromuscular deficits. Both of these patients underwent exploration, resulting in findings of normal muscle and no compartment syndrome.

Surgical decompression was recommended in all 9 patients with abnormal DVF but was refused by families of three patients because of otherwise deteriorating clinical status. Two patients with abnormal DVF, elevated compartment pressures, and neuromuscular deficits at initial examination underwent immediate fasciotomy and débridement of necrotic muscle. Both compartment pressures and DVF returned to normal in the 6 patients who underwent fasciotomy. In 15 patients, both compartment pressures and DVF were normal and all recovered without deficits.

No patient developed significant hyperkalemia. Elevations of CPK level were noted in four patients with abnormal DVF but not in any other patients. In all of these patients, fasciotomy either was refused, or they had come to surgical attention after irreversible neuromuscular damage had already occurred. One patient who presented 48 hours after a crush injury had CPK values of greater than 250 000 IU and suffered from acute renal failure associated with myoglobinuria.

COMMENT

Compartment syndromes may result in permanent loss of function and disability if early surgical decompression is not undertaken. Published results have often been poor, attributable to a lack of awareness of the condition due to its relative infrequency, and due to a lack of a means of definitively establishing the diagnosis before neuromuscular damage has occurred.[1,3,6,7] Physical examination, direct measurements of compartmental pressures, and nerve conduction velocity studies have all been employed in the study of patients at risk for development of compartment syndromes.

The diagnosis of a compartment syndrome is most often made on the basis of physical examination. In their review of the literature, Matsen and Krugmire[1] noted five signs and symptoms from published reports that were particularly suggestive of the diagnosis of a compartment syndrome. These included pain out of proportion to the clinical situation, hypoesthesia in the distribution of nerves within the compartment at risk, weakness of muscles within the compartment,

pain on passive stretch of involved muscles, and tenseness to palpation of the compartment. These five factors effectively define the presence of a compartment syndrome. However, no combination of these symptoms has been described that allows an early diagnosis before neuromuscular injury. Neither diminished or absent pulses nor skin pallor were reliable findings unless severe compromise was already present. Usefulness of physical examination is further limited in patients who are either unconscious, uncooperative, or unable to communicate, in those with nerve injuries, or in situations where the clinical findings are equivocal.

Unreliability of clinical signs has led to development of methods for direct measurement of compartmental pressures. The most widely used method for compartment pressure measurements involves the infusion technique described by Whitesides and colleagues[8] and others.[12,13] More recently, a solid-state transducer intracompartmental pressure monitor (STIC catheter) has become available, based on technology derived from the slit-catheter apparatus as described by Rorabeck et al.[14] Comparisons of this unit to the infusion method have shown it to be as reliable in determining compartment pressures (B. J. Awbrey, MD, P. S. Sienkiewicz, MD, and H. J. Mankin, MD, unpublished data, 1988).

Although use of either of these two methods allows determination of pressure within the compartment, such determinations have not proved to be uniformly reliable in the diagnosis of compartment syndromes, as an absolute upper limit of tolerable compartment pressure (resulting in no associated tissue damage) has not been established. Pressures of 55 mm Hg are consistently associated with neuromuscular damage unless decompression is performed.[9] Conversely, pressures of less than 45 mm Hg are less frequently associated with tissue loss, but are not invariably tolerated.[15] Patman[11] has recommended fasciotomy when compartmental pressures exceed 40 mm Hg. Pressures above 30 mm Hg, as determined by the slit-catheter methods, have been considered abnormal.[13,16]

Difficulty in establishing a maximal tolerable compartment pressure is no doubt related to the large degree of individual variation in tolerance of elevated pressures.[10] Other factors contributing to this dilemma are the presence of hypertension or shock, which may alter the compartmental pressure required to reduce blood flow, the presence of associated vasospasm and vasoconstriction, atherosclerotic disease, and arterial injury.

Progressive elevation of compartment pressure may be a more reliable sign of an evolving compartment syndrome than any absolute level of increased pressure. Serial determinations of compartment pressure, however, have the disadvantage of either requiring the presence of an indwelling catheter or multiple catheter insertions into already potentially ischemic and compromised tissues.

Measurements of nerve conduction velocities are less dependent on factors such as systemic blood pressure and vasomotor tone, are noninvasive, and accurately assess the adequacy of circulation to the nerves within a compartment at risk.[10] Disadvantages of this method are the requirement of specialized equipment and personnel to perform and interpret the study. The presence of nonischemic nerve damage resulting from the initial injury or preexisting condition may render the test unreliable.

These difficulties in establishing an early diagnosis of compartment syndromes led us to investigate other means. Current concepts of the pathophysiologic characteristics of the evolving compartment syndrome (Figure) emphasize the importance of progressive local venous hypertension leading to an eventual decrease in the arteriovenous pressure gradient sufficient to stop capillary blood flow.[1,17,18] This implies that increases in lower-extremity compartment pressure to levels

Proposed pathophysiologic progression of the compartment syndrome.

greater than the pressure within the recumbent tibial veins (7 to 16 mm Hg) are sufficient to collapse these thin-walled vessels and prevent venous flow. Furthermore, in this sequence of events, loss of venous flow should occur before reduction of flow through the capillary beds and subsequent onset of tissue ischemia. Loss of venous blood flow in an extremity at risk, easily determined at the bedside using transcutaneous Doppler ultrasonography, would then appear to be an early sign of an evolving compartment syndrome.

Recumbent tibial DVF is characterized by assessment of phasic flow, which occurs with the muscles relaxed and is associated with respiratory variation, and augmented flow, which occurs with manual compression of the calf muscles. In our study, loss of augmented flow always correlated with abnormal measured compartment pressures, and in four patients loss of phasic flow was shown to precede the development of abnormally elevated compartment pressure.

All patients who were found to have abnormal DVF had or subsequently developed neuromuscular deficits, even though measured compartment pressures remained normal (<30 mm Hg) in 2 patients. Interestingly, 2 additional patients were found to have elevated compartment pressures (35 and 40 mm Hg) but no abnormalities in DVF. Neither of these latter 2 patients had neuromuscular deficits, and no evidence of compartment compromise was demonstrated in either on exploration. Thus, in this series, direct measurement of the compartment pressure resulted in a false-positive or false-negative finding in 4 of 25 patients, and assessment of DVF was accurate in all cases.

Assessment of tibial DVF is easily performed and is noninvasive, allowing frequent serial examinations of the extremity at risk. We have also successfully used this method in the assessment of upper-extremity compartment syndromes. As a reliable screening procedure for the evolving compartment syndrome, assessment of tibial DVF should be determined in all patients in whom the diagnosis of compartment syndrome is entertained, but clinical signs are equivocal. Because of the correlation that exists between loss of tibial venous flow detected by Doppler ultrasonography and increased compartment pressures, persistent abnormalities in DVF should be considered an indication for other methods, including direct measurement of compartment pressure and perhaps decompression on the basis of DVF studies alone.

The authors wish to express their appreciation to Annabel Barber, MD, and Daniel Ciaburri, MD, who assisted in data collection, and to Philip S. Barie, MD, who reviewed the manuscript.

Discussion

WILLIAM W. TURNER, JR, MD, Dallas, Tex: The authors have given us a series with 100% sensitivity and 100% specificity. Yet all of the patients who had abnormal Doppler venous studies had either initial or evolving neurologic injuries, which suggests that perhaps these patients were not seen early enough to perform Doppler venous studies to diagnose the compartment syndrome in its earliest stages. This study seems to be an indictment of compartment pressures as a measure of evolving compartment syndrome. Two patients had obvious necrotic muscle at the time of fasciotomy with normal compartment pressure measurements.

What role might this technique have for patients who get "prophylactic" fasciotomies? Patients with combined arteriovenous injuries, particularly in the lower extremity, are often considered for fasciotomy at the time of the arteriovenous repair. Would this be an adjunct? I think it perhaps would be an adjunct in selecting some of those patients who might not need early fasciotomies.

What compromise in the test might cause significant direct trauma or significant direct muscle injury? There were only a few patients with such crush injuries in your series. Such significant direct trauma might interfere with venous return due to direct trauma in the tibial veins and might compromise the procedure to some extent.

It is intriguing that this test might be performed quickly and at the bedside and perhaps more invasively and by more people than direct measurement of compartment pressure. How long did it take you to learn to do this well? Can personnel other than physicians accurately perform this test, similar to the monitoring of arterial pulses by Doppler flow in the recovery room and the intensive care unit? How long would you advise monitoring DVF after an injury of the extremity? Over how long a period do you see the patient at risk for the development of a compartment syndrome?

DR PERRY: In one of our patients it was necessary to débride the anterior compartment, but the patient was completely rehabilitated. Unfortunately, this type of circumstance is not often encountered. We often recognize that the compartment syndromes are decompressed late; there is already dead muscle. This is another port for the beginning of an invasive infection with a hospital-based organism that may prove to be disastrous. Obviously, this is a small series subject to a type II error. In addition, we are dealing with a null hypothesis. Nine patients had a positive study; the remainder did not. The difficulty is that this needs to be confirmed in other patients.

It is our feeling that a progressive change, a sequential change, if you will, first loss of phasic flow, and then loss of augmented flow are indications of physiologic derangement. To us this would mean that the intercompartmental pressures may rise later. Truly compartmental pressures have been helpful. With the stick method it is possible to do this quite easily. But you must still place the needle in the compartment and do it repeatedly to have long-term surveillance. In many patients this will be for 2 or 3 days.

We have found that with the stick method, compartmental pressures are lower. The most interesting thing about measuring compartment pressures is the extreme variability that patients have to the tolerance of pressure. There is no certain upper limit, but 55 mm Hg seems to be universally injurious to muscle. The lower limits are not well known and perhaps 30 mm Hg is a little generous in these particular patients. Patients with crush injury would not necessarily be a bad group of patients even though the muscle is directly injured. One of the primary causes of compartment syndrome is bleeding within the compartment, sometimes in patients who are undergoing anticoagulant therapy and in others who have injuries. The mechanism then could be relieved by fasciotomy in that patient just as well. So this method may be of some help if there are no direct venous injuries.

Invited Editorial Comment

Compartment syndromes, because of their subtle presentations, may cause devastating morbidity, especially in unresponsive patients and those whose responses are masked by some aspect of therapy, such as controlled ventilation. Because there is a distressingly high incidence of tissue loss when the diagnosis is made after significant clinical signs are apparent, measurement of compartment pressures has become popular. Their variability, however, and patient variable tolerances, makes this the least reliable in the situation in which a highly sensitive and specific test is most needed. In this regard, Dr Jones and colleagues propose serial assessment of tibial venous blood flow using Doppler ultrasound.

The technique is based on the reasonable assumption that one of the first changes caused by elevation of compartment pressures will be compression of the low-pressure (7– to 16–mm Hg) tibial veins. Partial venous obstruction should result in loss of the spontaneous, phasic flow associated with respiration; complete obstruction will result in loss of the normal augmentation of flow that occurs when calf muscle is compressed. During a 12-month period of evaluating 26 patients at risk for compartment syndromes, the authors found 9 patients with abnormal venous flow, 7 of whom also had increased compartment pressure. Unfortunately, only 6 had fasciotomy; the other 3 refused surgery and ultimately had neurologic deficits. Five of the patients who had fasciotomy had both changes in venous flow and increased compartment pressures; all appparently had findings compatible with compartment syndrome, with only 1 having a permanent deficit. One patient with normal pressures but abnormal venous flow had necrotic muscle at surgery.

One can quarrel with a study of such a small number of patients and with the fact that most patients had peripheral vascular disease. Nevertheless, the data are consistent with the hypothesis and justify the authors' recommendation that others study this technique. It has the advantage of being quick, simple, noninvasive, and easily repeatable. It has the disadvantage of being totally observer dependent. Its widespread adoption will require attending physicians—and their house staff—to become considerably more proficient with personal use of the Doppler for venous examination than they are at present, but that is a laudable objective!

Myocardial Contusion

When Can the Diagnosis Be Eliminated?

Frank B. Miller, MD; Charles R. Shumate, MD; J. David Richardson, MD

• The clinical significance of various diagnostic tests and the length of monitoring required for myocardial contusion were evaluated in 172 patients. Cardiac isoenzyme levels, electrocardiograms, and echocardiograms were evaluated. Twenty-eight patients had a documented myocardial contusion based on at least one positive diagnostic study. The majority of positive studies were detected on admission and all positive tests were present within 24 hours. No patients developed positive diagnostic studies after 24 hours and, likewise, no clinical deterioration occurred late or in patients with a negative screening examination. The electrocardiogram and the clinical course were the primary determinants of the need for cardiac monitoring and therapeutic intervention. Cardiac isoenzyme levels had negligible significance on outcome, and the two-dimensional echocardiogram was not particularly valuable as a screening technique. If no abnormality is detected within 24 hours post injury, further investigation or monitoring does not appear warranted.

(Arch Surg. 1989;124:805-808)

Myocardial contusion has been described as a capricious syndrome that may go unrecognized initially and become apparent only when a serious cardiac complication develops.[1,2] Additionally, myocardial contusion has often been compared with myocardial infarction with the attendant implications for diagnosis and treatment. This concept has led to prolonged stays in monitored hospital beds and a host of diagnostic studies to establish or rule out the diagnosis. Many trauma units have recommended monitoring patients in intensive care units (ICUs) for several days when the diagnosis of myocardial contusion is considered.[3,4] Because of the large number of patients with blunt chest trauma from motor vehicle accidents, this has put a tremendous burden on the limited number of monitored beds in most hospitals.

We conducted a prospective study over a 2-year period on all patients with blunt chest injury suspected of having a myocardial contusion to answer the following questions: (1) What is the relative diagnostic value of electrocardiograms (ECGs), cardiac isoenzyme level determinations, and two-dimensional echocardiograms (2-D ECHOs)? (2) Who needs to be monitored and for how long? (3) What is the frequency of in-house deterioration of patients with unsuspected or known myocardial contusion?

METHODS

One hundred seventy-two consecutive patients who were suspected of sustaining a myocardial contusion entered a prospective protocol. Suspicion of contusion was based on the mechanism of injury or findings of chest wall injury on physical examination or chest roentgenogram. The majority of these patients had a history of direct blows to the chest, broken steering wheel accidents, or physical evidence of anterior chest wall injury, such as precordial bruising, fractured sternum, or anterior rib fractures. The protocol consisted of 72 hours of cardiac monitoring in an ICU or transitional care setting, serial ECGs, serial cardiac isoenzyme determinations, and 2-D ECHOs. The ECGs were obtained in the emergency department and at 12, 24, 48, and 72 hours after admission. Cardiac isoenzyme levels were measured on admission and at 8, 16, 24 and 48 hours after admission.

Echocardiography was performed and interpreted by the cardiologist in the majority of patients. Cardiac contusion was diagnosed when one or more of the following was present: (1) the creatine phosphokinase, CPK (MB), value was greater than 5% of the total CPK value, (2) an electrocardiographic or rhythm abnormality that could only be explained by cardiac injury, (3) abnormalities on a 2-D ECHO, and (4) cardiac contusion documented at autopsy.

RESULTS

Twenty-eight (16%) of the 172 patients had positive criteria for myocardial contusion. There were 23 men and 5 women whose mean age was 35.5 years (range, 16 to 68 years). The injuries were caused by motor vehicle accidents in 23 cases, auto-pedestrian accidents in 2 cases, crushes in 2 cases, and a fall in 1 case. A diagnosis of myocardial contusion was based on one or more of the following abnormalities: ST-T changes on ECGs in 10 patients, cardiac rhythm in 8 patients, electrical conduction in 6 patients, elevated CPK (MB) in 15 patients, 2-D ECHOs in 5 patients, and autopsy results for 3 patients.

Electrocardiographic abnormalities or shock were the only predictors of who needed monitoring or treatment. Patients with abnormalities of CPK (MB) and/or 2-D ECHO only never developed problems requiring treatment. Patients with ECG abnormalities and elevated CPK (MB) values were at no higher risk than patients who had ECG abnormalities only (Table 1).

Table 1.—Diagnostic Criteria

Positive Diagnostic Criteria*	No. of Patients†	Need for Monitoring	Need for Treatment
ECG only	7	5	3
ECG and CPK	8	5	1
ECG and 2-D ECHO	2	1	0
CPK only	6	0	0
2-D ECHO only	2	0	0
CPK and 2-D ECHO	1	0	0

*ECG indicates electrocardiogram; CPK, creatine phosphokinase; and 2-D ECHO, two-dimensional echocardiogram.

†Two patients who had autopsy-documented contusion and who died of shock shortly after admission were excluded from this table.

Table 2.—Time of Onset of Abnormality*

	No. of Patients				
	Emergency Department	12 h	24 h	48 h	72 h
ECG	17	0	1	0	0
Enzymes	8	7	0	0	0
Arrhythmias	8	3	1	0	0
ECHO	...	...	5	...	...

*ECG indicates electrocardiogram; ECHO, echocardiogram.

The time of onset of the various diagnostic abnormalities is shown in Table 2. Eighteen patients with ECG abnormalities developed these changes within 24 hours and 17 patients had the abnormalities present in the emergency department. No patient developed new ECG abnormalities after 24 hours and no patient who had an initially benign course developed delayed complications after transferring from an ICU environment. There was no delayed occurrence of myocardial failure or cardiac tamponade. No patient required a transfer back to a monitored-bed unit after being discharged from the unit.

Echocardiograms were obtained for 108 patients. Nineteen of these ECHOs were obtained for the contusion-positive group. Five 2-D ECHOs were abnormal, with 4 showing a small pericardial effusion and 3 showing a wall-motion abnormality. Two patients, who were not included in the contusion-positive group, had abnormal ECHOs and 1 of these patients had evidence of mitral and aortic valve disease felt to be rheumatic in origin. The other patient had a wall-motion abnormality from a preinjury myocardial infarction. The rest of the 88 ECHOs were read as within normal limits; however, 30 of these ECHOs were judged by the cardiologist to be technically inadequate. Intracardiac clot was not demonstrated on any of the ECHOs and the test had no effect on the treatment of the patients.

Three patients had ECG abnormalities presumed to be due to preexisting coronary artery disease. They had no associated enzyme or rhythm abnormalities. One patient had a preaccident myocardial infarction. While he had physical findings of a blunt chest injury, the ECG abnormality and enzyme values reflected myocardial infarction, and he had chest pains prior to the motor vehicle accident.

Four patients required specific treatment of complications believed to have resulted from myocardial contusion. A 23-year-old man with minimal injuries other than blunt chest trauma had severe bradycardia and a second-degree heart block requiring a transvenous pacemaker for 3 days. Lidocaine hydrochloride was required for frequent premature ventricular contractions in three patients. All four had rhythm problems present in the emergency department. No other patients required specific treatment related to myocardial contusion.

Nine of the 28 patients diagnosed with a myocardial contusion had one or more operative procedures requiring general anesthesia. Seven of these patients did not develop problems related to the contusion. Two of these patients died.

Three deaths occurred in patients with diagnosed cardiac contusion. A 47-year-old man died in the emergency department from bradycardia and resulting hypotension that was refractory to cardiac pacing and open heart massage. This patient had a prolonged vehicular extrication, profound shock, flail chest, and other injuries. Autopsy disclosed myocardial contusion that may have been a contributor to death. The second patient who died had a massive right-sided hemothorax requiring an emergency thoracotomy, and vigorous efforts could not resuscitate him. The postmortem examination showed a myocardial contusion but the clinical course suggested hemorrhagic shock as the primary cause of death. The third patient died of a head injury and the autopsy-documented myocardial contusion did not contribute to the death.

COMMENT

Blunt cardiac injuries range from disruption of the heart with immediate death to questionable myocardial contusion based on abnormal diagnostic studies with little clinical significance. There have been two overwhelming problems with the diagnosis of myocardial contusion. One has been the true natural history of the illness and the other has been the lack of a "gold standard" to confirm the diagnosis. Deterioration of patients with known or suspected myocardial contusion has been reported to occur late and be catastrophic.[1,2]

These reports emphasized that contused myocardium has a loss of reserve that may not be detectable except during periods of stress and increased oxygen demand. The logical result of this was prolonged monitoring of patients and the use of various diagnostic modalities as screening devices to identify patients at high risk. There has been a large divergence of opinion as how best to make the diagnosis of myocardial contusion and what the true significance of many proposed abnormal diagnostic modalities really means.[5]

Our data suggest that people who develop problems from myocardial contusion do so in the early postinjury period. All patients with ECG abnormalities, rhythm disturbances, or hemodynamic instability had these problems on presentation or within the first 24 hours. Control of arrhythmias, treatment of cardiac failure, and more specialized monitoring of patients requiring an operative procedure are the usual indications for therapeutic intervention in patients with contusion. All of our patients who required treatment or specialized monitoring for their contusion were easily identifiable on admission or within the first 24 hours. No patients developed late complications, such as cardiac tamponade or myocardial failure.

Cardiac isoenzymes are fairly specific for myocardial injury; however, the real clinical significance has not been shown.[6] In our patients without hemodynamic instability or ECG abnormalities, an elevated CPK (MB) value had no clinical significance. Elevated cardiac isoenzyme levels alone or in combination with other abnormalities did not increase the risk for arrhythmias or shock or the need for treatment. Based on these findings, we can no longer justify the performance of serial cardiac isoenzyme level measurements and we question whether the initial determination done at 8 hours after the injury is helpful.

An ECG should be obtained for all patients with blunt chest trauma. Patients with rhythm abnormalities or conduction

Algorithm for blunt chest injury.

defects need to be monitored in a specialized unit until their rhythm or conduction defects are resolved. When the initial ECG is normal or ST-T changes are present, 24 hours of monitoring in a telemetry unit is probably sufficient. Our data would agree with the Beresky et al[7] and Brunel et al[8] studies; both advocate less intensive and shorter periods of monitoring for these patients.

Frazee and associates[9] have advocated using 2-D ECHO in all patients with a CPK (MB) value greater than 5% of the total CPK value. In their hands, ECHO helped identify patients at high risk for arrhythmia. It also identified several patients with clot in the chambers of the heart who were then treated with long-term anticoagulation. Two-dimensional echocardiography was not helpful in our hands as a screening device, to assess the degree of injury, or to determine the need for treatment. Six of the 108 ECHOs were abnormal but none changed the need for treatment or monitoring. Other institutions have found the 2-D ECHO to be useful in evaluating the severity of the contusions.

There may be an increased incidence of cardiac complications in patients with wall-motion abnormalities that may signal the need for increased caution, especially if a general anesthetic is required. We believe that patients with a low cardiac output state should have ECHO to rule out a cardiac tamponade or evolving effusion. Our data clearly suggest that 2-D ECHO is an unnecessary, inefficient, and expensive tool to use for routine screening of all patients with suspected cardiac contusion.

Myocardial scans are advocated by some, but their clinical significance in patients in stable condition is very doubtful.[10,11] Clinical studies using myocardial scans have shown a wide variation in sensitivity of this method to detect patients with myocardial contusion. Rothstein and coworkers[12] studied 10 patients with blunt thoracic trauma considered to be at high risk for cardiac injury, using first-pass radionuclide angiography. All 10 patients had abnormal results with the study! Rothstein et al then advocated that radionuclide angiography should be used as a screening modality in the emergency department on all trauma patients with suspected myocardial contusion. Their conclusion demonstrates how far diagnostic studies have been used to establish a diagnosis of myocardial contusion without substantiating the test to have any clinical significance.

Based on our study, we have developed a protocol for patients with suspected myocardial contusions (Figure). Patients with multiple injuries, hemodynamic instability, rhythm disturbance, or conduction abnormalities are admitted to an ICU. Swan-Ganz catheters are strongly considered if the patient is over 60 years of age, has a history of cardiac disease, or is to undergo a major operative procedure. If hemodynamic instability persists despite adequate volume restoration, a Swan-Ganz catheter is used, regardless of age. Two-dimensional echocardiography should be considered in this group to rule out mechanical problems.

Consideration for discharge from the ICU is given once the rhythm disturbances and cardiac instability are stable for 24 hours. Patients in stable condition with no rhythm disturbances and minimal other injuries are admitted to a telemetry unit for 24 hours of cardiac monitoring. If no instability or rhythm disturbances develop, they are discharged from this unit and may be discharged from the hospital if this is their only injury.

This report does not intend to imply that myocardiac contusion is not a potentially life-threatening condition. Our group previously described a series of patients with cardiac contusion who required an intra-aortic balloon pump for myocardiac pump failure.[13] However, it does appear that the patients who will have major complications will generally have early clinical signs that should trigger a period of monitoring in an ICU. Furthermore, it appears that there has been a tendency to overuse ICU monitoring in the vast majority of patients. We hope that this report and several other recent reports with similar findings will aid the pendulum swing back to a reliance on clinical examinations and straightforward measures to diagnose and follow up such patients.

Discussion

PETER MUCHA, JR, MD, Rochester, Minn: Dr Miller and his colleagues are to be complimented on their attempts to further clarify our understanding of a condition that even today is best summarized by that now classic statement by Virgil: "And always with a cardiac contusion arise both doubt and much confusion."

The diagnostic dilemma is not in those patients with obvious signs of cardiac impairment immediately following injury, or is it in those patients in whom cardiac injury is documented at the time of autopsy. It is then too late. The problem is how do we go about identifying that subset of patients who would benefit from the implementation of special precautions without having to subject every patient at risk to expensive monitoring measures?

The methodology employed by this prospective University of Louisville (Ky) study is straightforward as they attempted to compare ECGs, CPK (MB) values, isoenzyme levels, and 2-D ECHOs. Based on a somewhat similar but not identical study from the Mayo Clinic, Rochester, Minn, we concur that CPK (MB), if evident, will be recognized within 24 hours following injury, and therefore, there is no rational basis today for advocating serial enzymes 2 to 3 days following injury unless dictated by a change in the patient's clinical course.

We also agree, as the Louisville group has said, that there are many cases where CPK (MB) values appear to be too sensitive as a screening tool. Based on our experience, we are not quite ready to confidently dismiss an elevated CPK (MB) value without subjecting that patient to a more definitive modality of diagnosis such as 2-D ECHO. We are also not quite ready to embrace electrographic monitoring alone for the first 24 hours as the sole or ideal screening tool. May I remind the authors of the many well-recognized electrographic changes seen in trauma patients as a result of hypoxia, catecholamine release, and electrolyte abnormalities. In this sense ECGs may be too sensitive.

What about the fact that it is based on many clinical and even autopsy studies that demonstrated that it is the electrophysiologically solid right ventricle that is most susceptible to injury, simply by the fact that it lies right behind the sternum?

Although arrhythmias in our experience were the most common consequence requiring therapeutic intervention in those patients with 2-D ECHO–positive cardiac contusion, 61% of our patients who had positive 2-D ECHOs had no electrocardiographic changes or arrhythmias whatsoever.

A criticism of this otherwise well-designed prospective study is the failure of the authors to adhere to the designed protocol in that only 108 of the 172 patients had 2-D ECHOs and only 19 of the 28 patients diagnosed as having a cardiac contusion had a 2-D ECHO. Even more disappointing was that over one fourth of the 2-D ECHOs were deemed technically inadequate. Therefore, any conclusions drawn about the role of a 2-D ECHO have to be interpreted cautiously.

We would agree that 2-D ECHO is impractical as a screening tool for every patient with blunt thoracic trauma, but we have found it to be a useful adjunct in being much more specific and definitive in objectifying structural and/or functional abnormalities in those patients who might have a cardiac contusion as suggested by either a CPK (MB) value or an ECG abnormality.

At first glance we were unable to correlate any increased risk among patients with cardiac contusion undergoing general anesthetic procedures. However, in a subsequent study conducted in conjunction with my anesthesia colleagues at the Mayo Clinic, we evaluated blunt trauma victims, specifically comparing those who had abnormal or normal 2-D ECHOs. Careful analysis demonstrated a statistically significant incidence of perioperative hypotension. This was characterized by an increased elevated central venous pressure or right-sided decreased cardiac reserve, which intraoperatively required drug therapy. There was an increased incidence of dysrhythmias as well, occurring among patients with abnormal 2-D ECHOs up to 2 months post injury. We recommended that Swan-Ganz hemodynamic monitoring should be considered in these patients for up to several months post injury.

DR RICHARDSON: If a patient has ECG abnormalities regardless of the cause, you are probably going to have to monitor that patient until his or her condition is stable. We admit ECG findings are nonspecific, but our management protocol has allowed us to simplify care for potential patients with myocardial contusion so that we don't have dozens of patients in busy hospitals taking up valuable critical care beds, which have become a tremendous national resource.

Dr Mucha also pointed out that only 70% of our patients did have 2-D ECHOs. He is right that we certainly would like to have had more. However, since over 100 patients participated in the study and no single case management was altered by having it, I am not sure how valid that point is. Clinical factors and the difficulty in conducting the study in a timely fashion were the reasons for the exclusions.

Again, to reemphasize, the purpose of this report is not to detract in any way from the potentially serious nature of myocardial contusion. We have described 4 patients who required an intra-aortic balloon pump for pump failure due to myocardial contusion. However, our data and experience indicate that patients who develop problems, either pump failure or arrhythmias, will generally do so in the first 24 hours. If we can monitor those patients well for those problems, and, generally, if they are not evident within 24 hours, then patients don't need to be kept in a high-cost monitored bed for longer than that period.

Intra-abdominal Injury Following Blunt Trauma

Identifying the High-Risk Patient Using Objective Risk Factors

Robert C. Mackersie, MD; Anurag D. Tiwary, MD; Steven R. Shackford, MD; David B. Hoyt, MD

• The initial physical examination is frequently unreliable in identifying patients with blunt trauma at high risk for having serious intra-abdominal injury. Intra-abdominal injury may be associated with specific injuries or risk factors, but the usefulness of such objective clinical criteria in predicting intra-abdominal injury has not previously been determined. The presence or absence of each of 11 clinical indicators and their association with serious intra-abdominal injury were analyzed in 3223 patients with blunt trauma. Linear and logistic regressions were used to determine which factors were significant predictors of an increased probability of intra-abdominal injury. Arterial base deficit less than −3 mEq/L, major chest injury, hypotension, and pelvic fractures were found to significantly increase the chance of intra-abdominal injury. Early diagnostic evaluation of the abdomen using diagnostic peritoneal lavage or computed tomography should be strongly considered in patients with blunt trauma who present with these associated factors.

***(Arch Surg.* 1989;124:809-813)**

The early recognition of intra-abdominal injury following blunt trauma is essential in preventing the morbidity and mortality associated with diagnostic delay. Diagnostic tests such as diagnostic peritoneal lavage (DPL) or computed tomography (CT) have augmented serial physical examination in many centers and have facilitated prompt diagnosis of intra-abdominal injury. The time, expense, and risk (albeit small) of associated complications, however, dictate that a selective approach to performance of DPL or CT be used. Selecting patients for diagnostic abdominal evaluation solely on the basis of the initial physical examination may result in a high incidence of missed injuries. Given the frequent unreliability of a benign physical examination, a number of other, more-specific objective criteria have been proposed. These have been used predominately as indications for performing DPL and include unexplained hypotension; altered sensorium (alcohol, other drugs, or head injury); major associated trauma; pelvic, thoracic, and spinal cord injuries; injuries above and below the diaphragm; and the need for prolonged anesthesia.

These indications for DPL (or possibly CT scan) have never been validated in a large series, and the relative importance of the various clinical factors (eg, hypotension) and associated injuries (eg, pelvic fractures) in predicting intra-abdominal injury has not been assessed.

This study was undertaken to (1) define objective criteria that may be used to identify patients with blunt trauma at high risk for significant intra-abdominal injury; (2) determine the relative predictive value of specific objective criteria; (3) determine the effect of multiple associated injuries or clinical factors on the incidence of intra-abdominal injury; and (4) derive a statistical model for predicting the probability of abdominal injury (P_{AI}) based on the presence or absence of these associated clinical criteria.

PATIENTS AND METHODS

The records of all major trauma victims who sustained blunt injury admitted to the University of California, San Diego Medical Center between January 1985 and July 1988 were reviewed. Patients transferred in from other facilities were excluded. For each patient, the presence or absence of a significant intra-abdominal injury (defined as an injury for which operative repair was required) was tabulated. Postmortem examinations were reviewed in patients who died without exploratory laparotomy to determine the presence of intra-abdominal injury. The presence or absence of each of five clinical factors (Table 1) and six injury types (Table 2) were also tabulated for each patient.

All the data recorded were in dichotomous or binary form (0 equals no abdominal injury or absence of clinical factor; 1 equals positive abdominal injury or presence of clinical factor). Two statistical models were used to analyze the binary data. The first is a simple linear equation of the form $P_{AI} = a_0 + a_1$ (chest) $+ a_2$ (base deficit) . . . , where chest, base deficit, etc, take values of either 1 or 0. While this model is appealing because of its simplicity, it may fail to be a good approximation of probability, since the calculation of variable "weights" (a_0, a_1, etc) using multiple linear regression depends on a normal distribution of the designated variables. To overcome this problem with dichotomous data, a logistic function of the form $P_{AI} = 1/(1+e^{-b})$, where

Table 1.—Clinical Factors Evaluated as Predictors of Serious Intra-abdominal Injury*

Clinical Factor	Definition
Base deficit	Calculated arterial base deficit <−3 mEq/L on admission arterial blood gas determination
Hypotension in field	Systolic blood pressure <100 mm Hg as documented by prehospital providers (EMTs, paramedics) at initial evaluation
Hypotension on arrival to hospital	Systolic blood pressure <90 mm Hg as documented by the primary physician at the time of arrival to the trauma center
Obtundation	Glasgow Coma Score <11 at the time of arrival to the trauma center

*EMT indicates emergency medical technician.

Table 2.—Injury Types Evaluated as Predictors of Serious Intra-abdominal Injury

Injury	Definition
Axial spine	Lumbar spine fractures/dislocations, sacrum and/or coccyx fractures/dislocations, thoracic spine fractures/dislocations
Pelvic fractures	Acetabulum, pubis, other (ilium, ischium, etc)
Lower-extremity fractures	Tibia fractures, tibia and fibula fractures, femur fractures
Head	Cortex, cerebellar, or brain-stem contusions or lacerations; subarachnoid, subdural, or extradural hemorrhage; other intracranial hemorrhage due to injury
Chest	Multiple fractured ribs, fractured sternum, flail chest, scapula fracture, crushed chest
Spinal cord	Hemiplegia, quadriplegia, paraplegia; C-1 through C-4 level cord injury; other cervical, thoracic, or lumbar level cord injury

$b = b_0 + b_1$ (chest) $+ b_2$ (base deficit) $+ b_3$ (pelvis) . . . , was also evaluated.[2,3] Calculations were performed utilizing BMDP software[4] on a VAX 11/750 mainframe computer (Digital Equipment Corporation, Maynard, Mass). For the logistic function, a stepwise algorithm was used that successively adds variables to the equation until no further improvement in predictive power is obtained by further additions. In this way, an "optimal" model is derived that only includes variables that have significant effect with respect to the dependent variable, intra-abdominal injury. High-risk factors were defined as those clinical factors or injury types, which, in the forward stepping logistic regression, resulted in significant improvement of the model (F to enter equals 3.0). Coefficients were determined that would allow the calculation of an approximate probability of significant abdominal injury on a given patient. The relative effects of the individual factors/injury types in increasing the chance of intra-abdominal injury were compared between the linear and logistic model.

The incidence of each factor/injury was determined alone and in association with intra-abdominal injury to allow comparison with data reported in previous studies. The incidence of intra-abdominal injury occurring with each factor/injury in isolation was also determined to allow comparison with the regression models.

The mechanism of injury was recorded for each patient, and the relationship between mechanism and incidence of intra-abdominal injury was also analyzed.

RESULTS

Of the 11 clinical criteria analyzed, 5 were found to be significantly associated with the occurrence of intra-abdominal injury, both for the linear and logistic model (Table 3). A base deficit of greater than −3 mEq/L and major chest injuries had the highest predictive power, followed by hypotension on arrival at the hospital, the presence of a pelvic fracture, and a history of hypotension in the field. Although the exact rank and order cannot be established from this regression analysis, the relative importance of the individual factors is supported by the close approximation of the derived regression coefficients to the actual incidence of intra-abdominal injury with each factor as an isolated occurrence (Table 4).

Table 3.—Predictors and Coefficients for Logistic and Linear Regressions*

	Logistic Equation		Linear Equation	
Clinical Factor	Coefficient	P	Coefficient	P
Constant	−2.09	<.001	.0138	<.01
Chest injury	.591	<.001	.1139	<.01
Base deficit	.556	<.001	.1145	<.01
Hypotension on arrival to hospital	.376	<.001	.1168	<.01
Pelvic fracture	.271	.002	.0512	<.01
Hypotension in field	.221	.012	.0277	.02
Spinal cord injury	−.632	.041	NS	NS

*NS indicates not significant.

The relative effects of individual and multiple factors on the incidence of intra-abdominal injury was approximated based on the calculated regression coefficients. The predicted increase in the incidence of intra-abdominal injury by the occurrence of each isolated factor alone was lower for the logistic function but follows a similar pattern (Fig 1).

The effect of multiple factors in increasing the incidence of intra-abdominal injury with multiple injuries is demonstrated by tabulating intra-abdominal injury from the raw data on patients with the combinations of the five major clinical factors: no major factors; base deficit alone; base deficit and chest injuries; base deficit, chest injury, and hypotension in the field; etc (Fig 2). The predicted incidence of intra-abdominal injury for this one particular sequence of multiple injuries/factors was then calculated based on the derived linear and regression coefficients. The logistic function may overestimate the incidence of intra-abdominal injury with isolated injuries, but it appears to provide a better approximation in cases of multiple injuries (Fig 2).

The coefficient for spinal cord injury, while not significant in the linear model, notably was found to be significantly negative in the logistic model (Table 2), suggesting that the presence of a cord injury had a modifying effect on the probability of intra-abdominal injury in the presence of other major clinical factors. This may be explained by the fact that cervical cord injuries were frequently associated with hypotension and a base deficit less than −3 mEq/L in the absence of major hemorrhage and intra-abdominal injury.

Thirty-seven (2.2%) of 1648 patients were found to have intra-abdominal injury despite the absence of all major clinical factors (Table 3). A more detailed review of the findings on initial physical examination and patient complaints showed that 35 of these patients had distinct abdominal tenderness noted at arrival to the hospital. An additional patient had abdominal distention, and only 1 patient (0.4%) had significant intra-abdominal injury without either an associated major clinical factor or suggestive findings on physical examination.

Diagnostic peritoneal lavage was the diagnostic procedure most frequently used and was performed on 1436 (45%) of

Table 4.—Incidence of Clinical Factors in 3223 Patients*

Clinical Factor	Incidence of Factor, No. of Patients	No. (%) of Patients With AI and Factor	No./Total (%) of Patients With AI and Isolated Factor
Chest injuries	615	136 (22)	17/158 (11)
Axial spine injuries	332	46 (14)	2/68 (2.9)
Pelvic fractures	332	65 (20)	2/38 (5.2)
Tibia or femur fractures	510	59 (12)	1/126 (0.8)
Closed head injury	380	52 (14)	1/49 (2.0)
Injury above and below the diaphragm	506	89 (18)	0/3 (0)
Hypotension in field	677	109 (16.5)	4/127 (3.1)
Hypotension on arrival to hospital	337	93 (27)	1/5 (20)
Obtundation	566	88 (15)	2/100 (2)
Base deficit <−3 mEq/L	568	131 (23)	11/98 (11)

No major factors	1648	37 (2.2%)	...
Overall incidence of AI	265 (8.2%)	...	...

*AI indicates abdominal injury.

Fig 1.—Relative regression weights of risk factors compared with actual data: single, isolated injuries. Solid bars indicate increase in risk predicted by linear regression; horizontally hatched bars, increase in risk predicted by logistic regression; and vertically hatched bars, observed increase in risk.

Fig 2.—Comparison of actual probability of abdominal injury for multiple injuries, with the incidence predicted by derived regression coefficients. Circle indicates observed incidence; triangle, predicted incidence by linear regression; and dotted graph, predicted incidence by logistic regression.

3223 patients. Of the lavages, 1236 were true-negative, 178 lavages were true-positive, 21 (11%) were false-positive, and 8 were false-negative (a false-negative rate of 0.65%, and a missed injury rate of 8/186 or 4.3%). Of the 21 patients with false-positive lavages, 20 were found to have hemorrhage produced by intra-abdominal injury not requiring operative repair. These included liver injuries (10 cases), splenic injuries (5 cases), pancreas injury (1 case), and mesenteric hematoma with hemorrhage (4 cases). False-negative lavages occurred with renal, diaphragmatic, duodenal, pancreatic, and a single small-bowel perforation. No delays in diagnosis or missed injuries occurred in patients who were observed and had no abdominal diagnostic procedures performed.

An analysis of the effect of mechanism of injury on the incidence of intra-abdominal injury (Table 5) showed that pedestrians struck by moving vehicles had a significantly higher incidence of intra-abdominal injury when compared with the total patient population.

Table 5.—The Incidence of Abdominal Injury With Mechanism of Injury

Mechanism	Incidence (%) of Abdominal Injury
Motor vehicle accident	125/1532 (8.1)
Pedestrian struck*	43/385 (11)
Falls/jumps	19/312 (6)
Assaults	19/264 (8.7)
Motorcycle accident	42/482 (8.7)

COMMENT

The process of diagnosing intra-abdominal injury following blunt trauma is of great interest to both trauma surgeons and emergency medical personnel. A number of previous reports have demonstrated that patients sustaining blunt abdominal trauma frequently die of treatable but unrecognized intra-abdominal injuries.[5-8] Missed injuries may be largely avoided with the use of various methods of early diagnostic evaluation, including DPL and CT. To institute a diagnostic workup, however, injuries must be suspected, and it is precisely that failure to suspect intra-abdominal injury in patients following blunt trauma that may lead to delayed diagnosis or missed

injuries. While the initial physical examination may serve as a clinical "trigger" to initiate a diagnostic workup, the frequent absence of physical findings, particularly in the presence of alcohol, other drugs, or associated injuries makes the physical examination unreliable in excluding intra-abdominal injury. The overall accuracy of the physical examination as a diagnostic screen has averaged 65% in a collected series,[9] and a number of studies have documented the unreliability of a "negative" physical examination as a means of excluding serious injury.[10-12] It is, therefore, useful to identify specific objective clinical criteria by which serious intra-abdominal injury may be suspected.

Previous studies have reported the frequent association of several clinical factors with hemoperitoneum. Gilliland et al[13] reported a 19% incidence of intra-abdominal hemorrhage associated with pelvic fractures, which is in close agreement with our data (Table 3). A 15% to 54% incidence of hemoperitoneum has been reported in association with major chest injury, and a 31% to 65% incidence in association with hypotension.[10,11] Davis et al[14] reported on the association between arterial base deficit and volume deficit and hemorrhage, often associated with intra-abdominal injury. None of these previous reports, however, was able to evaluate the association of abdominal injury with clinical factors. The data presented here provide a statistical validation of the importance of associated clinical criteria in "predicting" the probability of intra-abdominal injury. While it is difficult to draw definite conclusions from this analysis regarding the relative importance of each of the factors, it would appear from the collective data that hypotension on hospital arrival, the presence of major chest injury, and an arterial base deficit less than −3 mEq/L on arrival are the most powerful indicators of intra-abdominal injury. Pelvic fractures and a history of hypotension in the field appeared to be less powerful but are still important indicators.

Both linear and logistic models were evaluated in an attempt to derive a useful "rule of thumb" for estimating the approximate incidence of intra-abdominal injury based on associated clinical factors. Since all factor data are binary (0 or 1), it cannot assume a normal distribution, making the use of a linear regression less statistically appropriate. Despite this fact, the linear model still provides an approximate (if underestimated) prediction of intra-abdominal injury when compared with the logistic model (Fig 2), and may be of potential use in the clinical setting to set priorities with regard to the performance of DPL or CT scans. Notably absent from the list of significant clinical criteria were axial spine injuries, closed head injuries, obtundation from any cause, and injuries above and below the diaphragm (exclusive of chest or pelvic injuries, which were independently found to be significant factors). Sturm and Perry[15] reported a 21% incidence of abdominal visceral injury associated with fractures of the transverse processes. Rodriguez et al[11] reported a 45% incidence of hemoperitoneum in patients with a depressed sensorium. Neither of these previous studies took into account other associated injuries, however. The lack of predictive power of injuries above and below the diaphragm suggests that more minor injuries, such as humeral fracture, when associated with a tibia/fibula fracture are not mandatory indications for early diagnostic evaluation of the abdomen.

It is important to note that these data cannot be used to imply that the "nonsignificant" factors are unimportant in the evaluation of blunt trauma and that patients with these injuries can be assumed to not have serious abdominal injury. The regression results simply demonstrate that the addition of these factors does not meaningfully add to the overall predictive power of the model.

Most reports concerning DPL or CT scanning in blunt trauma avoid the thorny issue of when not to undertake a diagnostic workup. Most clinicians would agree that patients with an unimpaired level of consciousness and no major associated injuries may be safely observed. In patients with altered sensorium, the case is less clear. The rapidity, ease, and low incidence of complications reported for DPL[9,16,17] make the advocacy of a selective approach, under these circumstances, a bit tenuous. Reiner et al[18] advocated a selective approach to lavage in comatose patients with blunt trauma, particularly those without hypotension, physical examination results showing abnormalities, or truncal or femur fractures, but the authors based their conclusions on a small number of patients. We found no patient with obtundation to have intra-abdominal injury without the presence of at least one major clinical factor or suspicious results from a physical examination. In the group of patients without any major clinical factor present, only one had intra-abdominal injury in the absence of any physical signs of injury. While it is difficult to advocate abandoning the practice of objective abdominal evaluation in patients with a depressed level of consciousness, other factors, such as mechanism of injury and associated injuries, should be considered and management priorities ordered accordingly.

Mechanism of injury is increasingly recognized as an important component of trauma evaluation. Pedestrians struck had a significantly higher incidence of abdominal injury when compared with other mechanisms in this series (Table 4). A patient with these mechanisms, particularly in light of any associated injury, should be considered at high risk for intra-abdominal injury.

While this analysis dealt with objective risk factors, the subjective physical examination continues to be an important, if not a very accurate, indicator of intra-abdominal injury. This is supported by the fact that 37 of 38 patients with intra-abdominal injury in the absence of any of the five major clinical indicators had injury suspected on the basis of physical examination. Thirty-six of these patients demonstrated abdominal tenderness, and 23 actively complained of abdominal pain.

The analysis of the data presented here demonstrates that statistical modeling based on objective risk factors may be used to numerically approximate the probability of abdominal injury. Physical examination, although inaccurate as a diagnostic method, remains an important indicator of serious intra-abdominal injury when results are abnormal. Patients with large base deficits, hypotension, major chest or pelvic injuries, or abnormal results from a physical examination should be strongly considered for early diagnostic evaluation of the abdomen.

Data analysis was supported in part by grant M001-RR00827 from the Division of Research Resources, National Institutes of Health, Bethesda, Md. We thank Paul Schragg, MA, for his help with the statistical analysis.

Discussion

FRANK R. LEWIS, MD, San Francisco, Calif: This is the first instance of quantitative data being developed to evaluate predictors of abdominal injury, with a goal of having a model that would predict the relative likelihood of abdominal injury. I believe the authors have accomplished their objective. The performance of the model using either of the regression techniques closely parallels actual experience.

The weakness of this model is that the relative predictive power of the best of the factors that they evaluated is only about 10% when considered in isolation, and 20% when considered in association with other factors. Thus, these factors are not accurate enough to allow prediction of abdominal injury with any certainty and can serve only to increase one's suspicions. The danger of the use of this model is that the results will be interpreted as an indicator of injury or not, rather than as an indicator of the need for further diagnostic evaluation. The authors clearly understand and state this in their report, but I suspect it will be widely misunderstood.

I have three comments about the specifics of the study: (1) Many of the predictive factors that they evaluated are not binary but continuous. The authors correct these continuous variables to binary form by adopting threshold values for each. While this is statistically appropriate, it is not consistent with clinical reality. In this model, for example, a blood pressure of 85 mm Hg would have the same predictive value as a blood pressure of 40 mm Hg. I don't think that any clinician would accept this as realistic. (2) The category of injuries above and below the diaphragm is not very meaningful when chest and pelvic injuries have been eliminated. The intent of the authors is to get away from a slavish adherence to the criteria when injuries above and below the diaphragm are minor, but it carries a false message to those who do not read it carefully. (3) The definition used for abdominal injury is the presence of injuries that need operative repair rather than the simple presence of hemoperitoneum. Thus, patients with injury and hemoperitoneum who had stopped bleeding are related to the group without abdominal injury. While it is true that these patients would recover without laparotomy, this is cutting diagnostic precision a little too closely. Preventable deaths in trauma occur in patients who do not get a laparotomy when they need it, not in those who have negative laparotomies. (4) Defining abdominal injury as they have makes the results look worse than they are and serves to increase the pressure to avoid laparotomy in relatively inexperienced surgeons. This is clearly not a problem with the authors who had no missed injuries in their series, but it is a major problem in the non–trauma center hospitals.

In summary, this is an excellent effort to put abdominal evaluation on a more quantitative basis. At the same time, it clearly points out that the clinician is not in any danger of being replaced by a computer.

DR SHACKFORD: Thank you, Dr Lewis, for your very kind comments. As you appropriately stated and as we stated in the introduction, we were really trying to heighten awareness of the potential for intra-abdominal injury. Working at a teaching institution, our young residents and even our more senior residents really have the ability to perform what many of us now know are complete physical examinations to get the intuitive sense of injury, and this was an idea to heighten their awareness.

We totally agree with you that our selection of a linear type of index, for example, the base deficit of −3 mEq/L or the blood pressure, was entirely arbitrary. We would do it much to the same degree that we do when we look at a wide mediastinum. Clearly a mediastinum that is 14 cm at the aortic knob certainly heightens our awareness greater than one that is 8 cm. Nevertheless, the 8-cm one triggers the aortogram. A base deficit of less than −3 mEq/L is clearly abnormal and deserves investigation.

Fine-Needle Aspiration for Breast Mass Diagnosis

William H. Wolberg, MD; Martin A. Tanner, PhD; Wei-Yin Loh, PhD

• Our accuracy in diagnosing 464 solid breast masses by fine-needle aspiration was enhanced by a statistically based algorithm for distinguishing between benign and malignant epithelial cells. Epithelial cells were obtained from 378 breast masses by fine-needle aspiration; nonepithelial cells considered diagnostic of benign conditions were obtained from 66 breast masses, and 19 aspirations were considered unsatisfactory. Excluding one benign cystosarcoma, the algorithm gave 3 false-negative diagnoses and 16 false-positive diagnoses with 211 benign and 167 malignant samples. The overall clinical performance measures for the 444 masses from which diagnostic fine-needle aspirations were obtained and excluding the cystosarcoma were 0.98 sensitivity, 0.94 specificity, and 0.92 positive predictability. Masses diagnosed as benign by fine-needle aspiration can be followed up clinically. Intraoperative frozen section is needed before definitive surgery to determine invasion and confirm the diagnosis of some cytologically malignant masses.

(Arch Surg. 1989;124:814-818)

Fine-needle aspiration biopsy is an expeditious method of diagnosing breast masses. Although most researchers have shown enthusiasm for this method, some have voiced reservations.[1,2] Difficulties range from factors associated with obtaining the original sample to those associated with sample interpretation.

Fine-needle aspiration is operator dependent both in regard to obtaining and to interpreting the sample. To simplify and improve sample interpretation, we have developed a statistically designed method to distinguish benign and malignant breast fine-needle aspirations (Fig 1). We have defined the optimal sequence for key cytological criteria to be applied to diagnose fine-needle aspirations. Even with maximum diagnostic accuracy, cytological diagnosis is less accurate than histological diagnosis. Cytological overdiagnosis will result in performing cancer surgery for benign conditions and cytological underdiagnosis will result in the follow up of some cancerous masses. Most researchers have found that all fine-needle aspirations cannot be diagnosed and contain diagnostically "suspicious" and "unsatisfactory" categories for which a biopsy is automatically recommended.[4-14] Although definitive surgery is usually undertaken on the basis of an unequivocally malignant fine-needle aspiration, for masses with suspicious cytological criteria, a biopsy is performed before definitive surgery. Most authors will follow up clinically benign masses with an unequivocally benign fine-needle aspiration, but others recommend biopsy of all masses.[15-17] The risks taken for overdiagnosis and for underdiagnosis by these courses of management are reflected in test performance measures (Table 1). Diagnostic test performance measures include sensitivity (cytologically diagnosed malignancies divided by total malignancies sampled), specificity (cytologically diagnosed benign masses divided by total benign masses sampled), and predictability of a positive (total malignancies divided by total cytologic malignant diagnoses). Suspicious and unsatisfactory aspirates should be included in fine-needle aspiration test performance assessments. Test measurements vary from institution to institution, and one's own test measurements must be determined before fine-needle aspiration can be used clinically. These performance measurements predict the risks of overdiagnosis and underdiagnosis.

MATERIALS AND METHODS

A 3.8 cm 23-gauge needle was mounted on a 30- or 50-mL plastic syringe containing about 5 mL of air and was held in the right hand. The palpable breast mass was fixed between the fingers of the left hand, and the needle was introduced into the mass with several rotational passes while suction was maintained by the outward pressure of the right thumb on the underside of the syringe plunger. The fluid aspirated from cysts was discarded if it was not bloody. The material aspirated from solid lesions was expressed onto a gelatin-dipped slide. A similar slide was placed facedown on the aspirate, and the aspirate was spread as the slides were separated with a horizontal motion. Preparations were immediately fixed in 95% alcohol and processed in hematoxylin-eosin as described by Kline[18]

Eleven cytological features commonly described as distinguishing between benign and malignant aspirates were assessed on a scale of 1 to 10 with values of 1 representing morphologic features closest to those described as benign and 10 closest to those described as malignant.

Initially, a statistical algorithm[19] was developed by recursively partitioning a consecutive series of 37 benign and 69 malignant fine-needle aspirates to produce a dichotomous decision tree for diagnosing breast masses.[20] Optimal separation between benign and malig-

Fig 1.—The current decision tree–structured scheme with the classification of epithelial cells obtained by fine-needle aspiration of 378 solid breast masses as either benign or malignant (malig).

nant cytologic data was accomplished by evaluating clump characteristics when clumps were present and evaluating cell integrity when clumps were absent. The two clump characteristics used in our original decision tree were the extent to which epithelial cell aggregates were monolayered or multilayered (clump thickness), and cohesion of the peripheral cells of the epithelial cell aggregates (marginal adhesion) (Figs 2 and 3). Our original computer-generated statistically designed decision tree was modified to deal with errors that began to occur in the area of diagnostic overlap in specimens with intermediate clump thickness and intermediate marginal adhesion.[21] Analysis indicated that malignant preparations in the diagnostically ambiguous region had either grossly abnormal nucleoli (>8) and/or an abundance of single, free epithelial cells with intact cytoplasm (bare nuclei >6). On the other hand, benign preparations were characterized by normal nucleoi (≤8) and/or an abundance of single, free epithelial nuclei devoid of cytoplasm (bare nuclei ≤6) (Figs 4 and 5). The present decision tree incorporates these features (Fig 1).

To be considered a satisfactory fine-needle aspiration, epithelial cells must be obtained from aspirates of the breasts of premenopausal women but not necessarily from the breasts of postmenopausal women because epithelial atrophy occurs at menopause. Fine-needle aspirations from postmenopausal breasts are considered satisfactory if fibroconnective tissue fragments or cells diagnostic of a benign condition such as fat necrosis are obtained.[14] Biopsies are automatically performed on masses from which unsatisfactory fine-needle aspirations are obtained.

All malignant aspirates were histologically confirmed, but biopsies were performed on fine-needle aspiration–diagnosed benign masses at the patient's request only. The remainder of benign cytological determinations were confirmed by clinical reexamination 3 and 12 months after the aspiration. Surgical biopsies were performed on masses from which suspicious fine-needle aspirations were obtained and were considered true positives if they were histologically cancerous and false negatives if they were histologically benign.

RESULTS

Epithelial cells were obtained from 378 breast masses by fine-needle aspiration; nonepithelial cells considered diagnostic of benign conditions were obtained from 66, 19 aspirations were considered unsatisfactory, and benign epithelial cells were obtained from 1 benign cystosarcoma. Excluding the cystosarcoma, our diagnostic algorithm for epithelial cells gave 3 false negatives and 16 false positives with 211 benign and 167 malignant samples (Fig 1). Two of the false-negative aspirations were from pure tubular carcinomas. The overall clinical performance measurements for the 378 masses from which diagnostic fine-needle aspirations were obtained and excluding the cystosarcoma were sensitivity of 0.98, specificity of 0.94, and predictability of a positive of 0.92. Of the 20 masses of which biopsies were done because of unsatisfactory fine-needle aspirations, 14 were benign and 6 were malignant. Our accuracy diagnosing these 464 solid breast masses by fine-needle aspiration compared favorably with other reports (Table 1). We have no suspicious category, so to standardize the data from various series reviewed in Table 1, suspicious fine-needle aspirations were considered true positives if they were histologically cancerous and false negatives if they were

*All data were converted so that suspicious fine-needle aspiration results are considered true-positive if histologically positive and false-positive if histologically negative. Preparations considered unsatisfactory were excluded from the calculations of test performance measurements. Sensitivity was calculated by the formula true-positive/true-positive + false-negative. Specificity was calculated by the formula true-positive/true-negative + false-positive. Predictability of a positive was calculated by the formula true-positive/true-positive + false-positive. See the "Results" section for the number of total cancers in the present study.

Fig 2.—A graphic representation of the sample distribution for the two cytological classification parameters (nodes) of the original computer-generated binary decision tree, clump thickness and marginal adhesion, on 211 benign fine-needle aspirations. Cross-hatching indicates the area of diagnostic ambiguity based on these two criteria.

Fig 3.—A graphic representation of the sample distribution for the two cytological classification parameters (nodes) of the original computer-generated binary decision tree, clump thickness, and marginal adhesion on 167 cancerous fine-needle aspirations. Cross-hatching indicates the area of diagnostic ambiguity based on these two criteria.

histologically benign. The cystosarcoma (a stromal neoplasm) was the only mass from which benign epithelial cells were obtained and on which a biopsy was performed solely on clinical suspicion.

COMMENT

Fine-needle aspiration is a deceptively simple method of diagnosing palpable breast masses. Like any other test, the diagnosis made by fine-needle aspiration is not always correct. There are problems of suspicious and unsatisfactory preparations, of overdiagnosis, and of underdiagnosis.

Our series contained no diagnostically suspicious category because our goal was to positively diagnose by the cytologically based decision tree. Obviously, the closer the cytological criteria are to the diagnostic cut points, the greater the clinical suspicion that must be placed on the diagnosis. Our false-positive and false-negative preparations have been reviewed and no basis has been found to change the original classification grades. The cytological characteristics of the false-negative preparation were clearly benign: thin and tightly adherent clumps. In contrast, most of the false-positive preparations fell close to the diagnostic cut points, although one of the benign preparations was definitely cytologically malignant.

In most series,[4-14] clinically benign masses have been followed up when the cytological diagnosis is definitely benign. A biopsy is performed on suspicious aspirates and clinically suspicious masses. The main problem with underdiagnosis is that only a small sample is taken and the bulk of the mass is left in the patient. In contrast, the entire mass is usually excised for histological diagnosis. Because our sensitivity is

Fig 4.—A graphic representation of the benign samples in the diagnostically ambiguous zone classified as bare nuclei and nucleoli.

Fig 5.—A graphic representation of the distribution of cancerous samples in the diagnostically ambiguous zone classified on bare nuclei and nucleoli.

0.98, we follow up almost all cytologically benign lesions unless the patient requests removal. In our study, 29 patients requested removal of fine-needle aspiration–diagnosed benign masses. The cystosarcoma was the sole cytologically benign mass on which a biopsy was performed for clinical suspicion alone.

In the case of the cystosarcoma, our algorithm for epithelial cells gave a benign interpretation because cystosarcoma is a stromal neoplasm with benign epithelial elements. With our sensitivity of 0.98 and since we performed few biopsies on benign masses, two diagnostic delays occurred. The patients in whom these delays occurred still did not have positive nodes when the cancer was diagnosed. Two of the three false-negative aspirations occurred in pure tubular carcinomas, which, in addition to being difficult to diagnose cytologically,[22] behave in a relatively benign fashion.[23] In most series,[4-12,15-17] an unequivocally positive cytological diagnosis serves as the definitive diagnosis before mastectomy. We perform a biopsy on fine-needle aspiration–positive masses smaller than 3 cm with the patient under general anesthesia and obtain a frozen section as the first step of the surgical procedure. Definitive surgery often is done without preliminary biopsy for most cytologically diagnosed cancers larger than 3 cm. The preliminary biopsy and frozen section are done for smaller cancers to determine whether they are in situ or invasive, a distinction that cannot be made cytologically. The invasiveness of the cancer needs to be known to determine whether axillary lymph nodes are to be dissected. Our data and those of others indicate that nodes are unlikely to be involved with in situ cancers smaller than 3 cm in diameter. Lagios et al[24] found 11 instances of microinvasion among 24 duct carcinomas in situ

Table 2.—Lymph Node Metastases in Duct Carcinoma In Situ

Tumor Size	No. of Patients	No. of Patients With Axillary Nodes Examined	No. of Patients With Positive Nodes
<0.6 cm	20	3	1
0.6-3.0 cm	11	10	0
>3.0 cm	8	8	2

(DCIS) that were 2.5 cm or larger but found no microinvasion among 29 carcinomas smaller than 2.5 cm. Silverstein et al[25] found no instance of axillary metastases among 100 patients with DCIS who underwent axillary lymph node dissection. Our experience with 39 patients with DCIS is listed in Table 2. Eighteen of 19 patients with DCIS larger than 0.5 cm had axillary lymph nodes histologically examined. Two of these patients (tumor sizes, 3.5 and 7.0 cm) had positive nodes. Only 3 of 20 patients with tumors smaller than 0.6 cm had axillary nodes examined histologically, 1 being a patient whose presenting symptom was metastatic breast cancer in an axillary lymph node. The only breast cancer found in this patient was a 0.1-cm DCIS. Except for this patient, no axillary adenopathy was found or has developed in a patient with DCIS smaller than 3 cm. Therefore, axillary dissection or sampling is done only for DCIS larger than 3 cm and for invasive cancers of any size. For 3-cm and smaller cytologically diagnosed cancers, histological determination of invasion needs to be obtained by intraoperative frozen section. Confirmation of the cytological diagnosis is obtained incidentally. For larger cytologically diagnosed cancers, mastectomy is usually done without further biopsy—although rarely is a core-needle biopsy done.

We wish to emphasize two aspects of this study. First, and specifically, our statistically based algorithm is a good method for cytologically diagnosing breast masses. Second, and in general, the methods used to generate the algorithm are an example of the application of new statistical techniques to medical diagnosis.

This study was supported in part by Public Health Service grant CA-35464 from the Department of Health and Human Services, National Cancer Institute, Bethesda, Md.

Discussion

JOE BRADLEY AUST, MD, San Antonio, Tex: Essentially, if a patient has a palpable lesion of the breast, the accuracy of the technique the authors propose is such that they can plan definitive therapy in most patients from just fine-needle aspirates. Dr Wolberg indicates that if the lesion is 3 cm or larger they proceeded to carry out definitive therapy without further study. If the lesion is 3 cm or less, they performed a surgical biopsy to determine whether the lesion was in situ and did not require axillary dissection or axillary sampling. Using their decision tree, accuracy appears sufficient to warrant this particular approach. I commend them for this and hope that this approach will be adopted by others if they can maintain this level of accuracy.

One of the things that they have done that appeals to me as a surgeon is that they have been able to eliminate all those vague, suggestive diagnostic terms that pathologists and mammographers use to hedge, and despite their elimination, they have still been able to maintain a very impressively high level of accuracy.

But what disturbs me is the fact that 3 of 40 in situ carcinomas had axillary involvement. Perhaps this is a play on words, but if it is in situ by definition, it should not have any invasive potential and, therefore, should not have axillary metastasis. I think we should really reclassify the 3 in situ carcinomas that had metastasis as false negatives and accept the fact that the pathologist was mistaken three times because there must have been some invasive potential in those lesions diagnosed as in situ. Fortunately, only one of these occurred in an individual who had a lesion smaller than 3 cm in diameter.

LAWRENCE W. NORTON, MD, Denver, Colo: According to the abstract, almost one in five patients had nonepithelial cells in their aspirates. Was the criteria for malignancy used for epithelial cells the same as for nonepithelial cells?

JAY K. HARNESS, MD, Ann Arbor, Mich: The false-positive rate or the number of false positives was 16. That is an extraordinarily high number. In our experience here in Ann Arbor, at our Breast Care Center over the last 4 or 5 years we have had two false positives of a nearly equal number of fine-needle aspirations. Could the authors elaborate on such a high number?

MELVIN A. BLOCK, MD, La Jolla, Calif: Please comment on the role of large-needle or core-needle biopsy. Do you use that as a supplement or in any fashion to obtain histologic direction as far as invasiveness in some of these questionable lesions?

DR WOLBERG: First, I will answer the question concerning the cells used to diagnose nonepithelial malignancies. One needs to clarify that, by definition, adenocarcinoma is an epithelial malignancy. Therefore, malignant epithelial cells will be present in a carcinoma. Normal epithelial cells will be present in nonepithelial malignancies, such as in cystosarcoma phylloides. Some cases of cystosarcoma have been diagnosed by abnormal stromal cells obtained by fine-needle aspiration. The cystosarcoma that I aspirated in the present series yielded no stromal cells and was, therefore, cytologically benign. However, I performed a biopsy on it because it was highly suspicious clinically.

The false-positive rate of 16 brings up the point of the clinical use of fine-needle aspiration. I use fine-needle aspiration so I do not have to perform a biopsy on every lesion seen in the clinic. I don't want to have false negatives. I feel that missing a cancer is more detrimental than performing a biopsy on an additional number of cancers. With 16 false positives, it was necessary for me to perform a biopsy on lesions before undertaking definitive therapy. I am going to take some patients to the operating room for supposed definitive surgery with benign lesions. The general false-positive rate in my series allows me, as Dr Aust pointed out, to get off of dead center. My series reports no suspicious lesions. Cytologically suspicious lesions are specifically classified. In my series and in my literature review, I have classified as being a true positive any cytologically suspicious or positive mass on which a biopsy is performed and which is found to be cancerous. Any cytologically suspicious or positive mass found to be so through a biopsy and that comes back as benign is considered to be a false positive. That explains the high number of false positives in my series. I use a core-needle biopsy frequently to determine whether I am dealing with an invasive or an in situ lesion.

Concerning the question of the 3 of 39 cases of in situ carcinoma with positive nodes, I agree absolutely with Dr Aust. I think that indicates a pathologically underdiagnosed invasive cancer.

Oncological Aspects of Immediate Breast Reconstruction Following Mastectomy for Malignancy

Craig H. Johnson, MD; Jon A. van Heerden, MB, FRCSC; John H. Donohue, MD; J. Kirk Martin, Jr, MD; Ian T. Jackson, MD, FRCS(Glasg), FRCS(Edin); Duane M. Ilstrup, MS

• One hundred eighteen women treated with mastectomy and immediate breast reconstruction for carcinoma were evaluated for recurrence of disease and survival. Fourteen women (12%) suffered relapse of their cancer and 10 patients (9%) died of their disease during a median follow-up of 2.3 years. All seven local recurrences (6%) were detected at an early stage and treated without removal of the prosthesis. Recurrence of disease occurred more frequently in patients with involved axillary lymph nodes and larger tumors. Patient survival was adversely affected by nodal metastasis and the absence of tumor estrogen receptors. Adverse outcome in this series correlated to known prognostic factors for breast cancer. Disease-free and overall survivals were comparable with our previous experience with mastectomy alone for breast carcinoma. In the absence of any apparent negative impact on patient outcome, and because of the well-documented positive psychosocial benefit of immediate reconstruction, this procedure should be routinely offered to women with operable breast cancer.

***Arch Surg.* 1989;124:819-824)**

Today, the woman with breast cancer, as well as her attending physician and surgeon, face many therapeutic decisions. Clinical options pertain not only to surgical management of the malignancy but to the type of adjuvant therapy and to the cosmetic appearance of the breast following ablative surgical procedures. Immediate reconstruction of the breast, particularly when axillary nodal involvement is present, has been discouraged. Conventional teaching suggests a 2-year period of observation between mastectomy and reconstruction, and a recent edition of a major surgical text continues to recommend delayed breast reconstruction when adjuvant therapy is required.[1] The greatest concerns regarding the timing of reconstruction have focused on the alteration of mastectomy technique to accommodate immediate reconstruction and the ability to detect and treat locally recurrent breast cancer when a breast prosthesis is in place.

Since 1981, we have offered immediate reconstruction to patients with operable breast cancer regardless of nodal status. Previous review of our experience[2] showed excellent patient acceptance of immediate reconstruction. Several other studies[3-6] have documented a positive psychological impact following immediate reconstruction, including a more positive body image and decreased postmastectomy stress.

If mastectomy with immediate reconstruction can be done with low morbidity and no mortality, as has been demonstrated,[2] and if positive psychological and cosmetic benefits are evident, then the issue of immediate reconstruction centers on two important issues: (1) Does the presence of a prosthesis interfere with the detection and management of recurrent disease? (2) Are the recurrence rates and survival of women following immediate reconstruction different from those of women after mastectomy alone? This study focuses on the oncological follow-up and outcome of patients undergoing immediate reconstruction following mastectomy for malignancy in an attempt to answer these two questions.

PATIENTS AND METHODS

The study group consisted of 118 patients treated for breast cancer with mastectomy and primary reconstruction at the Mayo Clinic, Rochester, Minn, between 1980 and 1986. During the study period, patients with primary operable breast cancer were offered immediate reconstruction as a treatment option. A "breast team," including a general surgeon and a plastic and reconstructive surgeon, evaluated all patients preoperatively. For patients referred after breast biopsy elsewhere, all pathologic slides were reviewed at our institution prior to a definitive operative procedure.

A retrospective chart review was performed with attention to operative procedure, histologic and pathologic tumor variables, adjuvant therapy, and details of recurrent or metastatic tumor. The date of the last follow-up and patient status was recorded by return visit, telephone call to the patient, or correspondence with the patient's local physician.

Operative procedures performed for documented malignant disease included modified radical mastectomy, simple mastectomy, and subcutaneous mastectomy. Modified radical mastectomy was performed in a manner previously described.[2] A transverse or oblique incision was used, and the pectoralis minor muscle was left intact. Axillary dissection was performed on 110 of the 118 patients. Immediate reconstruction was performed with a variety of commercially available silicone prostheses, including expanders and implants. Breast prostheses (Dow-Corning, Midland, Mich; Heyer-Schulte, Goleta, Calif; and Surgitek, Racine, Wisc) were utilized and implanted in a subpectoral, subserratus muscular pocket. In one patient, transverse rectus abdominus myocutaneous flaps were employed with subsequent permanent implant placement.

Tumors were pathologically staged as follows: (1) stage 0, carcinoma in situ; (2) stage I, less than a 2-cm tumor, negative axillary nodes; (3) stage II, 2- to 5-cm tumor or positive axillary nodes with equal to or less than a 5-cm tumor; and (4) stage III, greater than a 5-cm tumor, axillary nodes positive or negative.

For 18 patients in whom biopsies were performed elsewhere, pathologic tumor data regarding size were unavailable. These tumors

were staged according to lymph node status and a review of preoperative clinical measurement. Estrogen receptor analysis was performed on all patients for whom adequate tissue samples were available, using a standard charcoal assay.

Adjuvant combination chemotherapy was offered to all premenopausal women with axillary lymph node involvement. Antiestrogen therapy was recommended for postmenopausal women with positive lymph nodes and a positive estrogen receptor assay.

Disease-free survival and survival to death were estimated using the Kaplan-Meier product limit method.[7] The effects of discrete variables on disease-free survival and overall survival were assessed with log rank tests.[8] Values of $P<.05$ were considered statistically significant.

RESULTS

Patient Data

Patients ranged in age from 23 to 79 years, with a mean of 50 years and a median age of 48 years. Fifty-two percent were premenopausal and 48% were postmenopausal at the time of mastectomy. Follow-up ranged up to 102 months, with mean and median follow-up of 2.5 and 2.3 years, respectively.

Clinical Data

Fifty-one percent of the tumors were in the right breast, 42% in the left, and 7% were bilateral. Forty-two percent of the lesions were located in the upper outer quadrant, 41% were central, and the remaining 17% of the tumors were divided between the lower outer and two inner quadrants.

Table 1 shows the operations performed for the different histologic tumor types. Twenty-one patients had modified radical mastectomy with a simultaneous simple or subcutaneous mastectomy of the contralateral breast, 13 for prophylaxis and 8 for synchronous malignancy.

Thirty-three patients in the stage II and III groups received adjuvant chemotherapy following ablative surgery. Another 17 postmenopausal women were given antihormonal therapy. One patient in the stage III group received adjuvant chemotherapy and radiation therapy for matted, positive axillary nodes. In no instance was adjuvant therapy delayed or impaired by the presence of a breast prosthesis.

Pathological Data

Table 2 shows the distribution of tumor variables affecting prognosis. The majority of women had grade 4 infiltrating ductal cancers less than 2 cm in diameter. Twenty percent of the patient population had noninvasive malignancy. Because of the favorable prognosis and lack of recurrence in this study with in situ carcinomas, the data were analyzed for both invasive and noninvasive lesions together and invasive malignancies alone.

Tumor Recurrence

Fourteen patients developed recurrent disease. The time to recurrence ranged from 1.5 to 32 months, with a mean of

Table 3.—Local or Local and Distant Recurrent Disease

Patient No.	Histologic Type	Lymph Node Status	Stage	Location	Time to Recurrence, mo	Status/mo
1	Invasive ductal	+	III	Subcutaneous; posterior chest wall	10	Deceased/15
2	Invasive lobular	+	II	Subcutaneous nodule; skeletal	32	Deceased/33
3	Invasive ductal	−	I	Scar	12	Deceased/24
4	Invasive lobular	+	III	Subcutaneous	28	Alive/54

7	Invasive lobular	+	II	Axillary drain site; skeletal	11	Deceased/12

Fig 1.—Top, Disease-free survival for the entire patient population. Bottom, Comparison of disease-free survival for patients with metastatically positive (bottom line) and negative (top line) axillary lymph nodes.

Fig 2.—Top, Disease-free survival of patients with less than 2-cm (thick line) and equal to or greater than 2-cm (narrow line) invasive carcinomas. Bottom, Overall survival of patients with less than 2-cm (thick line) and equal to or greater than 2-cm (narrow line) invasive carcinomas.

15.5 months and a median of 10.2 months. Three of 14 patients initially had locally recurrent disease only, 4 patients presented with both local and distant recurrences, and 7 patients had distant metastasis alone. Of the 7 patients with a component of local failure, the distribution of locally recurrent disease was as follows: 4 recurrences were in the subcutaneous tissues, 2 were in the mastectomy scar, and 1 was at an axillary drain exit site. The details of the 7 patients with local recurrence are shown in Table 3. None of the locally recurrent tumors were present deep to the pectoralis major or serratus anterior muscles. All local recurrences were treated with excisional biopsy and radiotherapy, chemotherapy, or both. No prosthesis required removal following excisional biopsy or radiation therapy.

Disease-free survival for all patients was 81% at 5 years (Fig 1, top). Recurrent disease was significantly more common in patients with positive axillary lymph nodes (Fig 1, bottom) ($P = .0001$). When patients with in situ cancers (there were no recurrences in this group) were excluded, recurrent disease was still more common in patients with invasive cancers who had positive axillary lymph nodes ($P = .0004$). Patients with larger invasive tumors were at significantly increased risk for recurrence (Fig 2, top) ($P = .004$). No difference in disease-free survival at 5 years was detected between premenopausal women (76%) compared with postmenopausal women (74%) with invasive breast cancers. Invasive tumors with positive estrogen receptor values recurred less often than estrogen receptor–negative cancers, but this was not statistically significant (disease-free survival was 74% vs 52%, respectively, after 4 years' follow-up) (Fig 3, top).

Survival

Ten of the 118 patients had died of disease at completion of this study, 1 of unrelated cause. The average time to death was 20.6 months, with the median time to death of 14.5 months. Survival of all patients at 5 years following mastectomy was 81% (Fig 4, top). Survival for patients with negative axillary lymph nodes was significantly better than that for patients with nodal metastasis (Fig 4, bottom) ($P = .0002$). This remained true when in situ cancers were excluded ($P = .004$). Women with estrogen receptor–positive invasive cancers also had statistically better survival (Fig 3, bottom). Survival was not found to be influenced by menopausal status (premenopausal women with invasive cancers [65%] vs postmenopausal [85%] at 5 years; $P = .3$), nor was it related significantly to tumor size in this study (Fig 2, bottom).

COMMENT

Spurred by a belief that survival of patients with breast cancer is more dependent on tumor biological features than local regional therapy,[9] and by an increased demand for better

Fig 3.—Top, Comparison of disease-free survival for patients with invasive cancers by positive (top line) and negative (bottom line) hormone receptor status. Bottom, Comparison of overall survival for patients with invasive cancers by positive (top line) and negative (bottom line) hormone receptor status.

Fig 4.—Top, Overall survival for all patients. Bottom, Comparison of survival for patients with metastatically positive (bottom line) and negative (top line) axillary lymph nodes.

cosmetic results after ablative surgery for breast cancer, breast-conserving operations have become commonplace. Prospective, controlled trials[10,11] have shown equivalent patient outcome for standard mastectomy and smaller tumor excisions followed by irradiation. The stark cosmetic contrast between these procedures has become the major reason for a woman opting to preserve her breast. Immediate breast reconstruction lessens this difference in cosmesis while maintaining the excellent local disease control of mastectomy and avoiding the routine requirement of adjuvant radiation therapy. For these reasons, plus excellent patient satisfaction and low morbidity of the procedure,[2] we are routinely offering mastectomy with immediate reconstruction as a treatment option for operable breast cancer.

Numerous investigations support the psychosocial benefits of immediate reconstruction. Women often feel disfigured or mutilated after mastectomy, and this has a substantial adverse impact on their psyche. When comparing women who were randomized in a prospective study to immediate reconstruction or no reconstruction, Dean et al[12] showed significant advantages to reconstruction. Psychologic morbidity was less, more women returned to work, they felt greater freedom in their choice of clothes, and were less repulsed by their appearance after reconstruction. Others have noted improved self-image, less psychologic turmoil, and a better patient outlook following reconstruction in uncontrolled experiences.[3,6] Furthermore, Wellisch et al[5] found no support for the previously held assumption that a woman must live with the mastectomy deformity before appreciating a reconstructed breast. Our previously reported experience[2] reflects the high patient satisfaction with immediate reconstruction, with 85% of patients advocating immediate reconstruction and 32% feeling their cosmetic result was perfect on a scale of 1 to 10. Breast reconstruction is a significant "quality of life" issue and must be given high priority in treating a woman with breast cancer.

There are economic factors favoring reconstruction at the time of mastectomy. Immediate insertion of a prosthesis avoids a second hospitalization and anesthetic for this procedure. Use of a permanent expander eliminates the need for expander-implant exchanges at a later date. The initial hospitalization is not prolonged by the placement of the implant,[2] and the morbidity from the simultaneous reconstruction is acceptable.[2,13] The recovery time from a single procedure is not excessive, and patient discomfort is lessened by avoiding a second operation.

Implantation of a silicone prosthesis has been feared as a potential promoter of tumor recurrence, but no evidence has been found to uphold this concern.[14] The presence of a bulky breast implant has also been seen as a potential obstacle to detecting local recurrence. Because most local recurrences develop in the skin, subcutaneous tissues, or regional nodal basins, rather than deep to the chest wall musculature, only rarely will a breast prosthesis camouflage a local recurrence. Our results confirm this observation. All local recurrences were detected at a small size in superficial locations. No deep

chest wall recurrence or en cuirasse lesion was noted.

Local recurrence risk following a mastectomy is a function of several tumor variables, including tumor size, lymph node metastases, and skin involvement.[15] Local recurrence is usually a sign of systemic disease and predictably these risk factors for local recurrence are also prognostic indicators for patient survival. Of the 60 patients in the group of Gilliland et al[16] who were eligible for reconstruction and who had local breast cancer recurrence, only 3 survived 10 years.[16] Of our 7 patients with local recurrence, 4 had concurrent detection of metastases, 2 subsequently demonstrated distant disease, and all but the last patient without detectable metastases have died of breast cancer. All seven of these local recurrences were excised without removal of the prosthesis, and further treatment was performed without interference by the implant. Radiation therapy can be delivered with a breast prosthesis in place without compromising delivery of an appropriate dose or increased morbidity.[17,18] Local recurrence of breast cancer following reconstruction is not to be feared because of delayed detection and treatment complications caused by the prosthesis, but rather because of the aggressive biologic features of the recurrent cancer and the resultant poor outlook for a woman with local recurrence.

Disease-free and overall survival in patients with carcinoma of the breast are dependent on patient (age, race) and tumor (invasion, size, metastasis, hormone receptor presence, rate of cell division) variables.[19] Patients in this series with involved axillary lymph nodes had significantly worse disease-free and total survival. Tumor size affected only relapse-free survival, while positive estrogen receptor status enhanced overall survival significantly. The 5-year survival of 81% for patients in this immediate reconstruction population compared favorably with the 87% 5-year survival at our institution following modified radical mastectomy alone.[20] This agrees with the findings of others.[13,21] Patient outcome is a function of tumor biology, not the presence of a breast prosthesis.

The timing of breast reconstruction following mastectomy has been an area of substantial contention. Arbitrary waiting periods of 6 months to 2 years have been imposed on women to allow their tumors to recur, thereby avoiding "unnecessary" reconstruction. While many breast cancers recur in the early postoperative period, the recurrence rate does not seem to slow until 10 years after treatment,[22] and breast cancer deaths occur in the treated population for 30 years or more.[23,24] Dowden and coauthors[25] showed that only 33% of the local recurrences following modified radical mastectomy and 33% of the patient attrition seen at 10 years developed in the 2 years after operation. Data such as these refute the rationale for a short waiting period to allow a breast cancer to show its intentions. Of even greater importance in considering this issue is the denial of improved patient satisfaction to those women whose disease does recur, as well as the delayed enhancement of self-esteem and outlook on life for those patients who do not suffer relapse before delayed reconstruction. Immediate reconstruction in a woman whose cancer recurs is not "wasted," given the psychologic benefit it provides at an acceptable risk. It should be kept in mind that the patient's next year may well be her last year.

We enthusiastically offer immediate breast reconstruction to those women undergoing mastectomy for operable breast cancer who desire this procedure. Patient acceptance of this technique has been outstanding, with minimal morbidity related to the primary procedure. Our operative team includes a general surgeon and a plastic and reconstructive surgeon to provide optimal oncologic and cosmetic results. The placement of a prosthesis has not compromised our resection technique. Improved cosmesis with fewer complications has been achieved with increased experience. In this early evaluation of our data, there is no evidence that a breast prosthesis interferes with adjuvant or recurrent disease therapy, the detection of recurrent breast cancer, and patient outcome. At present, the advantages of immediate reconstruction, including improved patient self-image and savings in time and money, are clear, while the potential adverse effects on cancer treatment and patient outcome are unapparent. It is our intention to follow the long-term course of this group of patients to confirm that the initial results, presented herein, are maintained.

Discussion

DAVID P. WINCHESTER, MD, Evanston, Ill: The authors are to be complimented for this well-done study that affirms what many surgeons treating breast cancer believe: breast reconstruction enhances the quality of life without compromising local control or cure. The option of immediate reconstruction makes total or modified radical mastectomy less mutilating and more acceptable to both patient and surgeon. Mastectomy in some form is still being performed in this country in the majority of patients. The American College of Surgeons' national survey in the 1970s showed that about two thirds of the patients with breast cancer were undergoing modified radical mastectomy, and approximately 8% were undergoing some form of breast conservation. A recent unpublished survey comprising over 30 000 cases revealed a tripling to 25% for breast conservation with the two thirds modified radical mastectomy number holding steady.

The preferred approach for reconstruction in this study was subpectoral implant or tissue expander. Others have suggested a superior result with the Tram flap, the possible trade-off being greater morbidity with the more extensive procedure. Scanlon and Murphy at our institution have demonstrated in experiments with mice that surgical trauma promotes tumor implantation. Tumor recurrence is highest in wounds induced by electrocautery, followed by laser and scalpel. More extensive surgery resulted in increased tumor recurrence. Wound healing also influenced recurrence: the earlier the wound, the higher the recurrence. I would ask the authors to comment on whether they see an increasing use of the Tram flap and whether tumor implantation in the large abdominal wound might be a hazard.

How many patients were truly definitively reconstructed immediately? The definition of immediate reconstruction is important for the patient. Did any patients opt for delayed reconstruction or was it offered? How is patient satisfaction measured?

Other than contralateral procedures for cancer, how many patients required breast reduction? Subcutaneous mastectomy was done in a few patients with lobular carcinoma in situ. Have the authors been pleased with the results? We have not. Finally, what percentage of patients in their larger population underwent breast conservation, and do they plan to compare patient satisfaction in this group with the present group?

RONALD G. LATIMER, MD, Santa Barbara, Calif: I enjoyed this report, which addresses a number of issues but did not address a number of other issues that worry some of our plastic and general surgeons. These would be flap necrosis, infection, seromas, and complications of an implant associated with chemotherapy. I would like to have the authors address these issues. In addition, we were not told what percentage of lesions had actual implants vs tissue expanders. The authors said the morbidity was acceptable, but they failed to show any data confirming that conclusion.

JAY K. HARKNESS, MD, Ann Arbor, Mich: I rise first of all to congratulate the other authors from the Mayo Clinic for an interesting presentation and the data. I also rise to support the conclusion of the authors. At the Breast Care Center at the University of Michigan, we routinely—and we are not as large a referral center as the Mayo Clinic—offer this option and agree with the Mayo Clinic that there is really excellent patient satisfaction and a feeling on the part of the women that something is being done.

I, too, am curious about tissue expanders vs full-size prostheses. You have not mentioned so-called touch-up procedures. Dr Woods from your institution talks about the need for touch-up procedures when I have heard him address other audiences. Also, I have a concern about the incidence of revision of the remaining breast.

DOMINIC ALBO, JR, MD, Salt Lake City, Utah: I would like to take a different tack, though, and wonder if we are not overusing this operation. There are a number of patients we have all had who, prior to their mastectomy, say they want to have a reconstruction. After their mastectomy and after they have had time to recover from their surgery, they are perfectly satisfied with their operation. In that group of patients, they would not have had to have this operation and the accompanying morbidity and mortality. Would the authors address this?

GEORGE A. HIGGINS, MD, Santa Barbara, Calif: Only 118 patients were described in this report, and I would like to know how many mastectomies were done at the Mayo Clinic during that time. The cases reported seem like a very small percentage of the total that were done during that time.

DR MARTIN: I would like to thank the discussants for a rather lively discussion. Dr Winchester, we appreciate that the data we are presenting today are rather short-term data. The mean follow-up is 2.3 years, and obviously we are going to have to carry out the follow-up much longer to really assess the impact of immediate reconstruction on breast cancer.

Plato pointed out that opinion differs from knowledge because the one errs and the other is unerring! Only time is going to let us know if this operation is truly equivalent to the superb modified radical mastectomy in terms of cancer management.

Many of the questions concern data that were reported in our first experience, ie, the first 100 patients that we studied and described several years ago. It is true that the reconstructions were not truly immediate, and that the one and only procedure that the patient had was at the time of mastectomy. Twenty-one of the first 100 patients subsequently went back for additional procedures, mainly nipple reconstruction. However, in 79% of the cases, the initial reconstruction was the sole procedure performed. Twenty-one of the patients in the first 100 had expanders and 79 had permanent Silastic prostheses placed at the time of reconstruction. Part of this was a judgment call based on the skin tension and the feelings of the plastic surgeon at the time of the procedure. As our experience progressed, we tended to use expanders more and more often. Becker prostheses, which offer expansion to the desired size, are our current implant of choice.

We have used Tram procedures occasionally. We had one in this group of patients with immediate breast reconstructions. The primary reason we have not used them more is because they are quite time intensive. We did offer delayed reconstruction to patients in this series who did not have immediate reconstruction during this time period. Rarely are we able to report on the percentage because of the referral type practice that we have.

Of the patients who subsequently had reduction mammoplasties in the opposite breast at the same time, about 21% had cosmetic procedures (27 at the same time, 24 later). This is necessary in about one fifth of the cases.

Dr John Woods at our institution has reported on his results with subcutaneous mastectomy in the treatment of high-risk patients and found that 5 invasive cancers developed of 1500 subcutaneous mastectomies in a large study that he put together.

Patient satisfaction was measured in terms of patient questionnaires. In that group, 32% rated the result as perfect and 85% commented that they would offer it to other patients as a good alternative to breast cancer.

The concern about wound implantation at the time of surgery is very reasonable. In a yet-to-be-reported study, we performed cytology washings of patients undergoing mastectomy in 153 consecutive mastectomies. Only 2 of those had positive cytologic finding and in none of those cases could we see that it made any difference in the overall outcome.

Dr Albo, we appreciate your comments about the reconstruction. Roughly 5% of the patients treated during this time had immediate breast reconstruction. The large majority did not.

What we tried to do with this study was to balance the dichotomy you see before you, and we think that immediate breast reconstruction offers the possibility of combining good cosmesis with the effective cancer treatment of a modified radical mastectomy. It is important that we follow up these patients to determine if they are truly equivalent operations, but we feel that this is certainly worthy of continued study.

Editorial Comment

I agree entirely with the thoughtful analysis and rationale for immediate reconstructive surgery described by Dr Johnson and his colleagues. Breast reconstructive surgery is an important component of cancer rehabilitation for many women with breast cancer. The results are excellent as described in this article. I include a plastic surgery consult *preoperatively* for virtually all patients who undergo mastectomy. For women who want to have breast reconstructive surgery the issue then centers around *timing* (immediate or delayed) and the type of reconstruction (usually an expandable prosthesis or a Tram flap). The majority of our patients who undergo breast reconstructive surgery at M. D. Anderson Cancer Center, Houston, Tex, have their reconstructive procedure performed under the same anesthesia as the mastectomy. The complication rate is not increased, and the patients are more composed and happy with the results.

Houston, Tex

The Outcome Index

A Method of Quality Assurance in the Special Care Area

Arthur S. McFee, MD, James Gilbert, MD

• A method of quality assurance for a surgical intensive care unit is described. A system outcome score is devised, incorporating only easily obtained objective components that reflect the likelihood of death. Through the use of a derived outcome index, the actual mortality rate is compared with the predicted mortality rate as a method of monitoring the quality of care provided. Subroutines exist to identify errors in data entry, to detect malicious interference in patient care, to add nonscoring components for the purposes of clinical studies, and to facilitate retrieval of a concise summary of the major events during the stay of every patient admitted to the intensive care unit.

(*Arch Surg*. 1989;124:825-829)

Literally millions of measurements are made in intensive care units (ICUs) in the United States yearly. They include the routine assessment of vital signs, frequent blood gas determinations, or complex derivations of cardiac output and work by computer-aided techniques. Each measurement can be used in assessing quality of care and acuity of disease or injury in the unit. In 1982, our institution was troubled by an allegation of malicious interference in one special care area.[1] At recurring intervals, we are visited by teams from the Joint Commission on Accreditation of Hospitals, which ever more stridently desires that each clinical area of the hospital give concrete proof of the quality of care provided in that unit. Although considerable differences exist in mortality rates in intensive care units across the country, it is generally assumed that care in these units is uniformly good. Relatively few university-based intensive care units, however, have directly examined the quality of care within their unit.

The considerations of quality assurance, accountability, and the assessment of malicious interference led us to attempt to use some of the routine measurements made in the surgical ICU (SICU) to develop a reproducible system of medical surveillance for our unit.[2,3]

METHODS

At the outset, we felt that such a system should have some explicit specifications.

1. It should rely only on routine observations made in the SICU.
2. It should evaluate the level of patient care, as it affects survival, to permit several comparisons: care offered at different time periods within one unit, care offered in different units within one institution, care offered in several units in many institutions at different times.
3. It should offer a means of detecting malicious interference.
4. It should be a practical system that would allow quality assurance studies on individual patient and unit outcomes.
5. It should reliably identify the patient for whom prognosis is virtually hopeless, as early as possible, to allow appropriate modification of care.
6. It should be simple, so that the data collection could be accomplished on each patient in less than 2 min/d. Additionally, the validity of the individual items of data collected should not depend on the experience, knowledge, skill, or judgment of the observer.
7. Data entry should not require more time than collection. Complete support for storage, retrieval, and protection from routine error should entail minimal expense for hard or soft computer ware.

Only one specific definition for outcome was used in this study. *Survival* means "discharged alive from the SICU."

It is important to point out that this system is significant in items that are not assessed. No attempt is made to grade the degree of illness or the progress of medical care. The extent and complexity of data collection is reduced at the expense of failing to detect the admission of patients not sick enough to qualify appropriately for ICU treatment. The system is not required to predict individual outcome, except with the most severely ill patients. In these instances, it is designed to detect those with no hope of survival for whom admission to the ICU or continuation of a stay in that area may not be appropriate. Predictions of mortality rates in less-ill groups of patients have not, in our experience as well as in that of others, been of clinical value.[4-8]

By not grading the severity of illness, the system will not routinely indicate the appropriate level of nurse staffing. Most nursing directors of ICUs, however, have their own scoring systems in place for this purpose. Nevertheless, the system does rely heavily on indicating interventional care; it can thus be used as an assessment of the acuity of nursing effort required in the unit.

The simple matter of defining survival as "discharged alive" from the SICU avoids the cost and inconvenience of follow-up of patients after they have left the area. Such follow-up studies are largely irrelevant to the assessment of quality assurance for care rendered within the unit.

In 1973, Pessi[9] reported a relationship between mortality and the degree of disturbance in vital function. Initiating this study in 1982, we felt that it was reasonable for us to seek simple clinical indexes of disturbed organ system function as a basis for a scoring system to lie within our previously described specifications.

To leave data collection as simple and mechanical as possible, we felt that the presence of certain clearly evident therapeutic interven-

tions would point to physiological dysfunction that would need not be assessed further. Patients on a ventilator probably have respiratory failure and could be scored as such without any further knowledge of the respiratory system. Similarly, a fraction of inspired oxygen (FIO_2) greater than 0.5 also points to significant respiratory dysfunction. The fact that vasopressors are in use generally suggests cardiovascular compromise, allowing failure of the cardiovascular system to be scored. Evaluation of complex relationships among such variables as systolic arterial pressure, pulse rate, pulmonary artery occlusion pressure, left ventricle stroke work index, stroke index, and systemic vascular resistance are completely avoided by simply using the presence of vasopressor support as a universal marker of cardiovascular system compromise. In our experience, as well as in that of others,[10] coma is associated with a poor prognosis, regardless of its origin; therefore, it is enough to note its presence without seeking the cause.

Similar simple indexes of dysfunction were sought for all organ systems; a total of 2321 patients were evaluated in two phases, each lasting 1 year (1983 and 1984). In each phase, the components (physiologic aberrations and therapeutic interventions) were noted, if present, at the time of admission and at 8 AM on each morning of the patient's SICU stay. Collected data were recorded in a database management system (VAX Datatrieve, Digital Equipment Corporation, Maynard, Mass) implemented in our Department of Computing Resources minicomputer (VAX 11-750, Digital Equipment Corporation).

At the conclusion of each data collection phase, customized subroutines written, within the Statistical Package for the Social Sciences (SPSS-X, SPSS Inc, Chicago, Ill), were run to check for errors in data entry; the medical records were obtained for any patient for whom errors were detected. These subroutines were capable of detecting such errors as nonsequential daily recording of components, duplicate records, invalid dates, incomplete entries, duplicate day numbers, invalid total system outcome score (SOS), patients discharged and readmitted on the same day with no change in component count, and patients being discharged with high component counts or dying with low component counts. All the data entry was performed by one of the us (J.G.).

Once errors were eliminated in each phase, stepwise logistic regression, performed using BMDPLR (BMDP Inc, Los Angeles, Calif), was used to determine which combination of the components was most commonly associated with nonsurvival. BMDP default values were used to enter or remove components. The results of phase I logistical regression were incorporated into the choice of components monitored in phase II. Similar analyses preceded the selection of the final components of the system for the second 2 years.

In 1983, the observations (components) assessed were as follows: Glasgow Coma Scale, greater than 9, 5 to 9, and less than 5; ventilator support; effective FIO_2 greater than 0.5; vasopressor use; blood urea nitrogen level to creatinine level ratio less than 10; urine output less than 0.5 mL/kg per hour for the 8 hours prior to the observation; temperature greater than 38.9°C in the 24 hours prior to the observation; white blood cell count greater than 20×10^9/L in the 24 hours prior to the observation; the use of immunosuppressants; the presence of coagulopathy; and age, 14 to 40 years, 40 to 60 years, 60 to 80 years, and greater than 80 years.

Partially based on the results of the logistical regression analysis, we changed the components in 1984 to the following: Glasgow Coma Scale, 5 to 9 and less than 5; ventilator use in the 12 hours prior to assessment, effective FIO_2 greater than 0.5; vasopressor use; blood urea nitrogen level to creatinine level ratio less than 10; urine output less than 0.5 mL/kg per hour for the 8 hours prior to the assessment; temperature greater than 39.4°C in the 24 hours prior to assessment; white blood cell count greater than 20×10^9/L in the 24 hours prior to assessment; white blood cell count less than 4×10^9/L in the 24 hours prior to assessment; the presence of barotrauma; and the presence of coagulopathy.

At the end of 1984, the data were again screened, errors were identified and eliminated, and a final logistical regression analysis was again performed to identify those items most commonly associated with death. The BMDP algorithm would admit only five components at standard P values for admission, and the surveillance system is now based on the following five observations (components): Glasgow Coma Scale less than 5; vasopressor use; effective FIO_2 greater than 0.5; urine output less than 0.5 mL/kg per hour for the 8 hours prior to the assessment; and the presence of coagulopathy.

Stepwise discriminant analysis, performed using BMDP7M (BMDP Inc), was then applied to the five components to determine their relative importance as indicators of mortality risk. The numerical values were obtained by a summation of the indexes of each component and an expression of each index as the percent of that total. The results are as follows: Glasgow Coma Scale score less than 5 equals 3.75; FIO_2 greater than 0.5 equals 1.00; vasopressor use equals 1.50; presence of oliguria equals 2.00; and presence of coagulopathy equals 1.75. The total is an SOS of 10.00 for individuals.

Fig 1.—System outcome scores (SOSs) of survivors and nonsurvivors during first 21 days of surgical intensive care unit admission. Bars indicate SDs; closed circles, patients who were discharged; and open circles, patients who died.

During the 2 years 1985 to 1986, an SOS was established daily for every patient in the SICU (n = 1947). At the end of each calendar quarter, the mean SOS for all patients admitted was determined. This figure was related to the fractional mortality for the unit for that quarter to derive an outcome index (OI), which can be represented by thefollowing equation: OI equals SOS times total number of admissions divided by total number of deaths.

The SOS is a quantification of interventional procedures and the specific medical status of an individual patient. It allows some prediction of mortality on admission (80%), which increases to greater than 87% accuracy 72 hours after admission to the unit and to 99% based on maximum SOS for the entire patient admission. It also permits some assessment of the amount of care required and a comparison of patients with one another with regard to the severity of disease or injury as they affect mortality. Outcome index, relating a cumulation of individual SOSs and overall mortality, allows one to assess the level and quality of care given in the unit, to relate the care to mortality, and to predict areas where suspicion of malicious interference may exist.

As we proceeded, some facts stood out. It rapidly became obvious that patients admitted with brain death secondary to head injury were a distinct subset in whom mortality was associated with a low SOS, since it was common that only one organ system failed. They were identified as such in the data entry program.

Ventilator support for longer than 12 hours had the same P value for entry as effective FIO_2 greater than 0.5, but the percent of those patients scoring for this observation who subsequently died was the lowest of all components evaluated. Effective FIO_2 greater than 0.5 was not only more specific in indicating mortality, but considerable crossover existed in patients identified. For this reason, we decided to continue to collect data on ventilator support for quality assurance reviews, but as a nonscoring component in the SOS system.

RESULTS

Patients who were brain dead as a result of head injury, in general, had a lower SOS on the day of death (5.75) than all other nonsurvivors (6.75). Usually, fewer interventional procedures are required with these individuals. In any month or quarter in which several patients who ultimately died were suffering from brain death secondary to head injury, the mean SOS was artificially low relative to the mortality rate. For this reason, 35 patients over 2 years, who were brain dead

Fig 4.—Component system outcome scores (SOSs) for survivors (shaded bars) and nonsurvivors (hatched bars). FIO_2 indicates fraction of inspired oxygen; GCS, Glasgow Coma Scale.

Fig 3.—Peak system outcome scores (SOSs) and mortality rate.

secondary to a head injury, were assigned a score of 6.75 on the day they were pronounced dead. They are excluded in creation of the component scores but are included in OI determination.

Mean SOS scores for survivors and nonsurvivors were significantly different for each of the first 21 days of admission into the SICU; survivors were less than 0.5, and nonsurvivors ranged from 2 to 4. Nowhere do these two curves, even with SDs, overlap ($P<.001$) (Fig 1). On a quarterly basis, the mean SOS of survivors averaged 0.28 and of nonsurvivors, between 3.75 and 6.0 ($P<.001$) (Fig 2). Similarly, individual peak SOSs were distinctly related to mortality (Fig 3).

When each component of the SOS was analyzed, wide differences were seen between survivors and nonsurvivors; $P<.01$ for all variables except FIO_2 greater than 0.5 where $P=.01$ (Fig 4). Similarly, the incidence of each component in the overall patient load was significantly different when one compared total patients with nonsurvivors. Table 1 demonstrates the mortality rates for each component of the SOS together with the incidence of that component in patients in the SICU; $P<.001$ in all cases (χ^2 analysis, survivors and nonsurvivors vs presence or absence of component).

Within each SOS grouping, there was a clearly defined mortality rate (Table 2).

No patient in our unit has survived a peak SOS of 8.5. Only one, in the 2-year group, has survived an SOS of 7.

COMMENT

The purpose of this study was to develop a practical system of medical care surveillance in the SICU, principally by indicating specific cases where review of medical care would appear to be indicated. The stimulus for development has been the increasing demands from the Joint Commission on the Accreditation of Hospitals and the state accrediting agencies for effective quality assurance, together with reported "epidemics" of death in some ICUs. The specifications for the system demand practicality, into which one must read brevity, simplicity, and objectivity.

A first requirement is a comparison of medical care across time periods. A crude index of medical care is the overall mortality rate. The OI attempts to add reliability and validity to mortality data by comparing quarterly mortality figures with a measure of the anticipated death rate derived from the presence of mortality risk components. Given the validation of these components in the "Results" section above, the OI should hold within a narrow range despite wide variations in the mortality rate if medical care is consistently effective in its treatment of these mortality risk factors. A deterioration in the level of medical care would appear as a declining outcome index and vice versa. In our unit, OI rose from 5.94 in 1985 to 6.82 in 1986 (Fig 5), suggesting a gradual improvement in the care provided. The range of OI representing 1 SD has a lower limit of 5.38 and seems a reasonable lower boundary, the penetration of which should trigger an audit of medical care for that quarter.

The peak SOS groupings represented in Table 2 were determined by cluster analysis and confirmed by χ^2 analysis and revealed a clearly defined mortality rate for each cluster. It would seem prudent to suggest that, at a minimum, all medical records of nonsurvivors in groups where the anticipated mortality rate is less than 50% should be reviewed for appropriateness of care. In the current study, this would mean 14 records of a total 1947. There is, however, a potential deficiency in the system in that patients who were admitted with low SOS, and as a result of less than expert medical management developed organ failure at a higher SOS resulting in death, will not easily be detected. No existing system completely eliminates this possibility; but in such a situation, the raw mortality rate will rise and remain high. A report constructed along the lines of Fig 5 should reveal that the occurrence of component scores as a percent of admissions will increase as will the mortality as a percent of occurrence. This is the opposite situation to that presented in Fig 5 and should be

Table 1.—The Incidence and Mortality Rates for System Outcome Score Components in Surgical Patients in the Intensive Care Unit*

Component	1984 Incidence	1984 Mortality	1985 Incidence	1985 Mortality	1986 Incidence	1986 Mortality

relatively obvious during any ongoing review of monthly and quarterly reports.

The detection of malicious interference in patient care is an important requirement for the system. Such interference in an otherwise nonterminal patient should appear as a sharp increase in the number of deaths in patients with peak SOS of less than 5 or in an OI that falls below 5.38 with a rising mortality rate. However, if malicious interference results in organ failure and the patient's demise is delayed until after the next scoring interval has occurred, it may not trigger an audit on the basis of death with an inappropriate peak SOS, although it may well precipitate a fall in the OI below 5.38.

Patient data collection and data entry have at all times met the requirement for a maximum total time of less than 2 minutes per patient. When the data collector is knowledgeable about the patient, collection time is 30 seconds per patient. Data entry, if done on a daily basis, seldom exceeds 10 minutes for 12 patients.

The query-by-forms method of searching the database allows a multiplicity of queries and comparisons to be answered at a few key strokes. Table 1 alone provides the basis for a quality assurance review. It is a simple matter to determine such items, for example, as the mortality rate of patients who are admitted in coma and shock. The database could be queried for patients with a Glasgow Coma Scale score less than 5 and receiving vasopressor support on the day of admission, thus identifying patients who meet these criteria and permitting their medical records to be obtained for further review. The result, based on our patient database in this group, was a 90% mortality with six survivors, over 2 years, ranging in age from 24 to 69 years. It is a simple matter to add other pertinent items to the data collection card as nonscoring components of the SOS as was done with ventilator support.

No patient has ever survived a peak SOS of 8.5; until very recently, no patient of a population of greater than 1500 had survived a peak score of 7. It was for some time thought that a score of 7 or higher was incompatible with survival. However, as critical care expertise improves, it seems reasonable to anticipate that upper limits will gradually be pushed higher as was our experience in this case. This survivor of an industrial accident was massively injured and received over 300 U of blood and blood products and is now back at work, demonstrating that considerable caution must be exercised in using a scoring system to determine that survival is never possible once a certain score point value is attained. Withdrawal of active medical support should only be undertaken on an individualized patient basis in the presence of appropriate clinical indications supported, but not dictated, by a patient's scoring system.

Computerized data collection in the ICU is often centered on the concept of collecting every conceivable data item, including vital signs, fluid and drug therapies, and laboratory investigations. These data are then stored in a format in which multiple queries and comparisons can be made at any time for the purpose of identifying trends in relationships that may be useful in the future and for equally unspecified studies of patient care, either on an individual patient or general unit population basis. In our experience, the volume of data produced, except where a select group of specific patients is identified, is so huge it overwhelms the capacity of the personnel involved to collect it accurately and completely in the first place and to utilize it effectively once it is collected. Our system attempts a more pragmatic approach in which limited data about vital organ systems are accurately collected for each and every patient, allowing evaluation of broad aspects of patient care to be undertaken. Within these limits, specific patients can be identified, permitting more detailed informa-

tion to be obtained from medical records.

Essential elements of the system are a simple data entry screen, the presence of data error detecting subroutines, query by forms for data retrieval, freedom to incorporate nonscoring components, and integration with the Statistical Package for the Social Sciences to produce the SOS and OI statistics as well as to identify patients in whom sudden and severe deterioration has occurred. To improve availability of this system, work is in progress to produce documentation and an image of the scoring system that will contain all the essential elements that can be distributed on floppy disks for personal computers (International Business Machines, Armonk, NY, or compatible equipment) in which the personal computer equipment version of the Statistical Package for the Social Sciences has also been implemented.

The SOS and OI appear to offer the possibility of effective quality assurance for medical care in ICUs through surveillance. The OI may facilitate comparison of the quality of medical care between different time periods within the one unit or between different ICUs. The peak SOS may possibly be useful to indicate patients in whom prognosis is hopeless and withdrawal of active support is indicated. It may also indicate patients in whom it is appropriate to undertake a chart review or assess the quality of medical care provided. The concept of patient data collection based on the ability to indicate specific medical records likely to satisfy a clinical study, rather than attempting to collect all known facts about every patient admitted to the ICU, may be a practical solution for a number of hospitals and researchers engaged in clinical studies.

We have used this system in the SICU of Medical Center Hospital in San Antonio, Tex, over the past 4 years. Each month, at clinical management team meetings for the unit, mortality is reviewed. Patients dying who were brain dead on entry to the unit, or became so afterward, are not reviewed. Patients whose SOS is greater than 5 similarly are not reviewed unless such a score develops late in the hospital course or there is sudden increase in SOS from one day to the next. The maintenance of an OI of consistent magnitude from month to month allows us to state with a degree of certainty that care provided in the unit has been kept at an appropriate level despite variations in degree of patient illness. An increasing OI reflects an improved outcome relative to the mortality risk.

Subsequent to the period of this study in July, August, and September 1987, we observed a sharply decreased OI with an unchanged mortality rate. We were able to trace this observation to several factors: the SICU respirology service was not offering appropriate intervention when indicated; general surgery senior house staff were not effectively reviewing patients on a daily basis for appropriateness of care; and communications between respirology and the surgery services had sharply deteriorated. Each of these issues was addressed and subsequent reviews have seen a return to standard levels.

Apart from this observation, we have seen no instances of sharp rises in patient mortality with unreasonably low SOSs or sharp rises in mortality with a decreasing OI. Any incident of an unexpected or sudden change in condition, resulting in mortality, is reviewed; so far, each such incident has had a rational explanation. We have found the system to be so sufficiently simple and effective that it should be able to be utilized even in small community hospitals without specialists, intensivists, or resident staff.

Nonoperative Treatment of Perforated Duodenal Ulcer

Thomas V. Berne, MD, Arthur J. Donovan, MD

• This report concerns 35 adult patients in whom perforation of a duodenal or prepyloric ulcer was treated nonoperatively between July 1979 and April 1988 at the Los Angeles County–University of Southern California Medical Center, Los Angeles. Each patient had pneumoperitoneum with clinical evidence of peritonitis, and a gastroduodenogram documented a sealed perforation. The ulcer was believed to be acute in 27 patients and chronic in 8. These 35 cases represent 12% of 294 cases of duodenal and prepyloric peptic ulcers with perforation treated during the same period. An intra-abdominal abscess developed in 1 of the 35 patients. Reperforation did not occur. The mortality rate for the 259 cases treated operatively during this period was 6.2%; the mortality rate of the 35 cases treated nonoperatively was 3%. Duodenal ulcer can be safely treated nonoperatively when a gastroduodenogram documents self-sealing.

***(Arch Surg.* 1989;124:830-832)**

Despite several encouraging reports of successful nonoperative treatment of perforated duodenal ulcer,[1-8] surgeons nearly always prefer operative management unless severe medical illness prohibits celiotomy. The Surgical Service of the Los Angeles County–University of Southern California Medical Center, Los Angeles, has had a long-standing interest in the treatment of perforated duodenal ulcer, including selective nonoperative therapy. For the last 25 years, the water-soluble contrast media upper gastrointestinal series (WS-UGI) has been used in some patients to determine which ulcers are leaking and which have spontaneously sealed.[1,4] The surgeon is "unblinded"; if present, the spontaneous seal is secure and the peritonitis will almost invariably resolve.[2,3,5] Nonoperative treatment can be selected for patients with perforation of an acute ulcer who are very likely never to need an ulcer-curative operation.[6-9] The effects of peritoneal soilage and the ulcer are managed with antibiotic therapy, nasogastric suction, and suppression of gastric acid secretion by H2 blockers. Additionally, the WS-UGI has made it possible to identify those critically ill patients in whom the perforation seals and for whom an operation to close the perforation can be avoided. This report reviews our recent experience with selective nonoperative management of perforated duodenal ulcers.

PATIENTS AND METHODS

The patients included in this study had perforated duodenal ulcers treated nonoperatively between July 1979 and April 1988. The protocol for the management of perforated duodenal ulcer has been developed based on experience at our medical center[2] and at the University of South Alabama.[3] The Figure shows the basic strategy followed. Patients with a history of abdominal pain suggesting peptic ulcer disease or a history of use of antacid or H2 blockers for a period of greater than 3 months were considered as having chronic ulcer disease. Documentation of a peptic ulcer on either endoscopy or an upper gastrointestinal roentgenographic study 3 months or more before perforation was also considered as indicating chronicity. Such evidence includes an ulcer crater, bulb deformity, or scarring. Patients with presumed chronic ulcer disease who were reasonable operative risks were appropriately prepared and taken to the operating room for an ulcer-curative procedure. However, patients with presumed chronicity who were judged to be poor operative risks received a WS-UGI (gastroduodenogram) study.

The WS-UGI studies were done by a senior radiology resident or an attending radiologist who looked for evidence of peptic ulcer disease, such as a crater, scarring, or extraluminal leakage. The study was considered indeterminate if the duodenum could not be seen clearly due to pylorospasm or if no ulcer crater was identified.[4]

After WS-UGI, any patient originally studied because there was not historical evidence of chronicity but found to have roentgenographically demonstrated duodenal scarring was considered to have chronic ulcer disease and was treated surgically. Patients with chronic ulcers who were believed to have a high operative risk and did not show leakage on a satisfactory WS-UGI were started on an initial plan of nonoperative therapy. Those with presumed acute ulcer disease with no roentgenographic evidence of chronicity and without leak shown on WS-UGI were started on a planned nonoperative approach.

A critical aspect of this method of nonoperative management is the necessity for reassessment of the patient every few hours by physical examination. If evidence of peritonitis progresses, or if there is not evidence of regression by 12 hours, surgery is indicated to rule out another cause of peritonitis or releaking from the ulcer. Therapy with intravenous fluids, broad-spectrum antibiotics, nasogastric tube suction, and H2 blockers should be instituted. Once there is resolution of clinical peritonitis, as demonstrated by a soft and minimally tender abdomen with active bowel sounds and a lessening of the fever and leukocyte count, the nasogastric tube can be removed. This is usually on about the fourth or fifth day. Slow refeeding with antacids, H2 blockers, and bland liquids is progressed to a semisolid diet. Oral H2 blockers are continued after hospital discharge. Late follow-up consists of endoscopy 6 to 8 weeks later. This study reports the results of this management policy on selected patients treated nonoperatively.

RESULTS

Thirty-five (12%) of the 294 cases of duodenal, pyloric channel, and prepyloric peptic ulcers with perforation treated during the nearly 9-year period reviewed had nonoperative management. Each patient had clinical evidence of diffuse peritonitis on physical examination and pneumoperitoneum demonstrated on abdominal or chest roentgenograms. There were 29 men and 6 women, ranging in age from 19 to 62 years (mean, 34.9 years). Thirty-four ulcers were duodenal and 1 was prepyloric. The ulcer was believed to be acute in 27 patients and chronic in 8.

Nonoperative therapy was abandoned in 2 cases due to concern with the rate of resolution in the physical findings of peritonitis. A freely leaking perforation was not found in either case. The only morbidity that delayed hospital discharge was 1 patient with delirium tremens. Another patient returned to the hospital 6 days after discharge because of fever. She required one percutaneous and one operative drainage to cure a pelvic abscess containing the organism *Eikenella corrodens*. Reperforation did not occur. Mean (± SD) hospital stay was 7.9 ± 3.3 days. The mortality rate for the 259 patients treated operatively during this period was 6.2%; the mortality of the 35 patients treated nonoperatively was 3%. The 1 death in this latter group occurred in a woman

with widespread metastatic breast cancer, which included both liver and bone, who was receiving prednisone for severe hypercalcemia at the time of her perforation. The major goal of her therapy was to contain the painful consequences of peritonitis. This patient had the one perforated prepyloric ulcer that was treated nonoperatively.

COMMENT

Self-sealing of the ulcer perforation is critical to the concept of nonoperative management. We know that this process can occur spontaneously. As early as 1843 Crisp[10] reported self-sealing of perforated ulcers. This was followed by additional reports of spontaneous closure by Battams[11] in 1883 and Hall[12] in 1892. The first attempts at induction and maintenance of sealing by nasogastric tube suction were by Wangensteen[13] in 1935. Bedford-Turner[14] in 1945, Taylor[15] in 1946, and Seeley and Campbell[16] in 1956 reported planned nonoperative treatment of patients with perforated duodenal ulcer. Taylor[5] continued these studies and refined many aspects of this type of management.

These early attempts were plagued by the inability to determine which patients had ongoing leakage and which had self-sealed perforations. Berne and Rosoff[2] carried out extensive studies in nonoperative treatment of perforated ulcers at the Los Angeles County-University of Southern California Medical Center during the 1960s and 1970s. They utilized the WS-UGI to identify the presence or absence of active leakage, referring to this as "unblinding the surgeon." In more than 350 proved cases of perforated duodenal ulcers examined by that method, 40% were found to be sealed at the time of a WS-UGI that was performed within a few hours of admission. Following a plan of careful observation similar to Taylor's,[15] results were excellent. Donovan and associates[3] reported the results of selective treatment of perforated duodenal ulcer at the University of South Alabama. Eight of 10 patients without leak shown on WS-UGI were treated nonoperatively and recovered without incident.

Despite these reports, there has not been much enthusiasm for adopting a selective nonoperative approach to perforated peptic ulcer disease. Most surgeons have been satisfied with suture closure of the perforation, particularly if the duodenum is pliable. Additionally, ulcer-curative surgery in the presence of acute peritonitis has been clearly shown to be as safe as suture closure for all but critically ill patients.[17-19] The likelihood of developing additional complications ultimately requiring operation is generally high, reportedly 43% to 60%, in patients with chronic duodenal ulcer treated by suture closure of a perforation.[20-22] Therefore, many surgeons believe that an ulcer-curative operation should usually be done at the time of perforation.[21]

We agree that aside from cases where there is high operative risk, this is the correct approach for nearly all perforations of chronic ulcer disease with sealing shown on WS-UGI. While there are several surgical options, including vagotomy with pyloroplasty, highly selective vagotomy with ulcer closure, and vagotomy with antrectomy, a discussion of definitive operative management is beyond the scope of this report.

In perforation of acute duodenal ulcer, most of the available information indicates that there is less likelihood for a late complication requiring an ulcer-curative operation, reportedly 11% to 20% of cases.[6,20,22] In fact, it appears that the percentage of perforated acute ulcers may be increasing as shown by the study of Boey et al.[23] That study also documented relatively little difference in subsequent ulcer morbidity between perforated acute and chronic ulcers in Hong Kong. Another recent study by Wara and associates[19] from Denmark verifies the older data, with a low symptomatic ulcer recurrence rate in patients with perforated acute duodenal ulcer treated by suture closure. Therefore, it has seemed reasonable to us to avoid an ulcer-curative operation, with occasional disabling sequelae, in perforation of acute ulcer disease. Because of the imprecision in distinction between acute and chronic ulcer, the unpredictability of the subsequent course of disease, and the minimal side effects of highly selective vagotomy, some authorities have recommended this as an acute phase operation for almost all perforated duodenal ulcers.[24] We have not adopted that policy. Suture closure, rather than an ulcer-curative operation, is recommended if an acute phase operation is done.[18,19] The need for this operation can be questioned if it can be accurately documented that the perforation has

already sealed. The only value of an operation will be to wash out the peritoneal cavity. This is also true if the patient with a self-sealed chronic ulcer had prohibitive operative risk factors.[8] We recommend nonoperative treatment under these circumstances.

Concern over peritoneal soilage has led surgeons to believe that it is important to carefully empty and wash out the peritoneal cavity with large volumes of saline at the time of operation. The results are quite gratifying, as large volumes of foul fluid are often removed. However, the actual benefit of this part of the operation is not so clear. Rosoff, in discussion of Donovan et al,[8] reports that of 109 patients treated nonoperatively during the acute phase, only 3 developed intra-abdominal abscesses. There was no such complication in the 8 patients treated nonoperatively by Donovan and only 1 such case in the 35 patients described here.

Though there has also been concern about the ulcer releaking, this has been a very unusual occurrence. In the studies reported by Berne and Rosoff,[2] this occurred in only 2 of 109 patients treated nonoperatively. Donovan et al[3] reported no releaks, and there were none in the patients described here. If nasogastric suction is maintained for several days and refeeding is started slowly under the cover of antacids and H2 blockers, the likelihood of releakage seems quite small.

In this report, one prepyloric lesser curative ulcer was included along with the other duodenal ulcers because of their recognized physiological similarity. However, corpus gastric ulcers are a clearly different problem, being more difficult to manage nonoperatively because of more frequent releakage, bleeding, recurrence, and the specter of malignancy. The nonoperative management of a sealed gastric perforation is inappropriate unless the patient faces a prohibitive operative mortality.

When compared with emergency operative intervention, a similar outcome can be achieved with nonoperative management of perforated duodenal ulcers shown to have sealed by WS-UGI study. Familiarity with this option for management may have its greatest value in the security with which the surgeon can adopt a nonoperative course in a clearly high-risk patient. However, this knowledge provides surgeons the opportunity to avoid celiotomy in perforated acute ulcer disease. It is even possible that selective nonoperative management may become a more desirable option if the severity of chronic duodenal ulcer disease were to wane due either to some inherent change or to the advent of increasingly effective medical therapy.

CONCLUSION

A WS-UGI study can reliably document self-sealing of a perforated duodenal ulcer. With such information, nonoperative therapy can be selected by the unblinded surgeon, with confidence that the seal should be highly secure and that peritonitis should nearly always resolve uneventfully. These observations permit the surgeon to adopt nonoperative therapy in selected cases, such as when operative risk is excessive or when only closure of the perforation is contemplated.

Invited Editorial Comment

Simple closure of a perforated duodenal ulcer carries minimal mortality in the average-risk patient. In healthy individuals, the safety and benefits of immediate definitive ulcer surgery for acute as well as chronic ulcers have been established by prospective controlled randomized trials. Thus, as Berne and Donovan conclude, nonoperative therapy has most to offer in patients who are poor operative risks or in those with a low risk of ulcer recurrence.

The 6% mortality rate in their healthier patients undergoing surgery is no lower than the average literature figure for unselected series of patients who underwent surgery. This implies that some poor-risk candidates were not identified preoperatively or that they had persistent leaks. Patient stratification by predictive risk factors is needed to judge meaningfully the merits of nonoperative therapy. In a prospective study done by my colleagues and me,[8] of three validated risk factors (shock, serious coexisting medical illness, and perforation exceeding 24 hours' duration), the operative mortality after closure was 45% and 100% in patients with two and three risk factors, respectively. If the poor-risk patients in the present series were comparably ill, then the 3% mortality rate achieved would argue most convincingly in favor of nonoperative management. Thus far, no group has been able to emulate their success with nonoperative treatment in critically ill patients, many of whom are moribund on presentation.

Given the lower risk of ulcer recurrence in acute as opposed to chronic ulcers, one might opt for nonoperative treatment instead of closure. If laparotomy were necessary because of persistent leakage, either simple closure or immediate proximal gastric vagotomy in healthy patients would be preferable to truncal vagotomy or gastric resection, which incurs more side effects.

The use of a water-soluble contrast study to confirm self-sealing of a perforation together with close patient monitoring to detect clinical deterioration are crucial to successful nonoperative management. Hence, nonoperative treatment may not be feasible in hospitals where emergency radiological services or intensive patient surveillance are limited.

Catheter Aspiration for Simple Pneumothorax

Experience With 114 Patients

Ralph E. Delius, MD; Farouck N. Obeid, MD; H. Mathilda Horst, MD; Victor J. Sorensen, MD; John J. Fath, MD; Brack A. Bivins, MD

• Between 1983 and 1987, 114 adult patients with 131 pneumothoraces were treated utilizing catheter aspiration for simple pneumothorax as an alternative to tube thoracostomy. The causes of simple pneumothorax were as follows: 79 needle-induced, 36 spontaneous, and 16 traumatic. Thirty-eight of the pneumothoraces were small (<20% of volume), 55 were moderate (20% to 40% of volume), 36 were large (>40% of volume), and 2 were of unknown size. Overall, catheter aspiration for simple pneumothorax was successful in 90 patients (69%). The success rate was 75% with needle-induced, 53% with spontaneous, and 75% with traumatic pneumothoraces. Small pneumothoraces were successfully managed with catheter aspiration for simple pneumothorax in 87% of patients, moderate-sized in 60%, and large in 61%. There were three complications (2.3%), including one hemothorax and two retained sheared catheter tips. The average cost per patient was $868 for catheter aspiration, and $6402 for a tube thoracostomy. These data support catheter aspiration as a safe, cost-effective, and successful technique for managing simple pneumothorax.

***(Arch Surg.* 1989;124:833-836)**

Simple pneumothorax is a frequently seen clinical problem. The most common causes for simple pneumothorax include spontaneous pneumothorax, trauma, intravenous drug abuse ("pocket shooting"), and iatrogenic causes such as central line placement, thoracentesis, or rib block. Conventional treatment of simple pneumothorax has been placement of a chest tube. While usually successful, tube thoracostomy is painful, requires several days of hospitalization, and is expensive. Several investigators have tried simpler, less invasive techniques for reexpanding the lung in the treatment of pneumothorax.[1-8] A pilot study performed at this institution (Henry Ford Hospital, Detroit, Mich) suggested that catheter aspiration for simple pneumothorax (CASP) was a reasonable alternative to tube thoracostomy for managing a simple pneumothorax.[6] This current study reviews a more extensive experience with this technique.

Accepted for publication March 11, 1989.

METHODS

A prospective study to evaluate CASP was initiated in 1983 and continued through 1987. Only patients older than 16 years of age with a pneumothorax not complicated by pleural effusion, hemothorax, multiple trauma, respiratory distress, or hemodynamic instability were entered into the study. Patients who met the entry criteria were treated according to the CASP protocol outlined in Fig 1.

Catheter aspiration for simple pneumothorax was carried out as a sterile procedure in the emergency department. The patient's chest wall was prepared with povidone-iodine (Betadine) solution and draped with sterile towels. The fourth or fifth intercostal space at the anterior axillary line was chosen for needle insertion. A 1% lidocaine solution was used for local anesthesia. A 16-gauge needle was advanced above the superior rib margin cephalad at approximately 60° into the pleural space. A soft guide wire was then advanced through the needle. An 8F radiopaque polytetrafluoroethylene (Teflon) catheter was passed over the guide wire into the pleural cavity. The guide wire was removed, and a three-way stopcock and 50-mL syringe were connected to the catheter. The intrathoracic air was then aspirated. Full expansion of the lung was signaled by the inability to evacuate further air from the pleural cavity or the sudden onset of coughing. A chest roentgenogram was obtained to confirm aspiration.

If the first CASP was unsuccessful, a second aspiration attempt was immediately performed and a second chest roentgenogram was obtained. If successful, the catheter was taped in place and the stopcock closed. Another chest roentgenogram was obtained 6 hours after the aspiration attempt. If the lung was still expanded, the catheter was removed. The patient was then discharged home with instructions to return immediately to the emergency department if symptoms recurred.

For the initial 61 patients enrolled in the study (study group 1), if a small residual pneumothorax was present on the roentgenogram taken after 6 hours, a chest tube was placed and the patient was admitted to the trauma service. For the subsequent 53 patients (study group 2) (Fig 2), a persistent pneumothorax following CASP was managed by connecting a Heimlich valve to the aspiration catheter. Another chest roentgenogram was obtained 1 hour later. The Heimlich valve was left in place if satisfactory lung expansion was obtained. If the pneumothorax was still present, the Heimlich valve was attached to a pleural suction canister, which was placed on 20-cm water suction. A follow-up chest roentgenogram was obtained 1 hour following placement of the apparatus to suction. If complete expansion was obtained, the apparatus was left to suction. If a pneumothorax persisted, a chest tube was placed. All patients who required use of a Heimlich valve, with or without suction, or who required placement of a chest tube were admitted to the trauma surgery service.

Fig 2.—Flow diagram outlining the catheter aspiration for simple pneumothorax (CASP) treatment protocol for the 53 patients in study group 2. CR indicates chest roentgenogram.

RESULTS

A total of 114 patients with 131 pneumothoraces were included in the study. Nine patients presented with bilateral pneumothoraces and 5 patients had repeated episodes of pneumothorax. There were 67 pneumothoraces on the right, 64 on the left. The ages of the patients in the study ranged from 17 to 76 years with an average age of 35 years. There were 66 men and 48 women in the study.

All patients were hemodynamically stable on arrival in the emergency department. Virtually all patients presented with complaints of dyspnea and/or pleuritic chest pain. The duration of symptoms varied from less than 1 hour to several days. Respiratory rates ranged from 16 to 40 breaths per minute.

There were 79 needle-induced pneumothoraces, 36 spontaneous pneumothoraces, and 16 traumatic pneumothoraces. The patients with traumatic pneumothoraces did not have any associated injuries. The pneumothorax size was estimated by the technique of Rhea et al.[9] Thirty-eight of the pneumothoraces were small (<20% of volume), 55 were moderate (20% to 40% of volume), 36 were large (>40% of volume), and 2 were of unknown size.

Overall, catheter aspiration was successful with 90 pneumothoraces (69%). In the first portion of the study, involving 76 pneumothoraces in 61 patients, the success rate of catheter aspiration was 76%. The treatment failures in the initial group were all managed with chest tube insertion. In the subsequent 53 patients with 55 pneumothoraces, the initial catheter aspirations were successful with 32 pneumothoraces (58%). The addition of the Heimlich valve successfully managed 10 pneumothoraces (18%). The Heimlich valve with pleural suction was required for 7 pneumothoraces (13%). Only 6 pneumothoraces (11%) in the latter part of the study required tube thoracostomy.

Needle-induced pneumothoraces were successfully managed with catheter aspiration in 59 patients (75%) (Table 1). In study group 1, consisting of 61 patients, there were 57 needle-induced pneumothoraces and 11 (19%) of these 57 required tube thoracostomy. No patients in study group 2, with 22 needle-induced pneumothoraces, required tube thoracostomy. The success rate of catheter aspiration in this latter study group was 59% (13/22). The addition of the Heimlich valve was required in 6 patients (27%) of this group. The remaining 3 patients (14%) were successfully treated with the Heimlich valve placed on pleural suction.

Table 1.—Success Rate: Modality vs Cause

	No. (%) of Patients			
Modality	**Needle-Induced**	**Spontaneous**	**Trauma**	**Total**
Catheter aspiration	59 (75)	19 (53)	12 (75)	**90** (69)
Heimlich valve	6 (7)	4 (11)	. . .	**10** (8)
Heimlich valve and suction	3 (4)	4 (11)	. . .	**7** (5)
Chest tube	11 (14)	9 (25)	4 (25)	**24** (18)
Total	**79 (100)**	**36 (100)**	**16 (100)**	**131 (100)**

Spontaneous pneumothoraces were successfully managed with catheter aspiration in 19 patients (53%). A total of nine spontaneous pneumothoraces (25%) required tube thoracostomy, five in study group 1 and four in study group 2. Of the latter study group, the addition of the Heimlich valve was required in 4 patients (11%), and Heimlich valve with pleural suction in 4 additional patients (11%).

Traumatic pneumothoraces were successfully treated by catheter aspiration in 12 patients (75%). All four traumatic pneumothoraces (25%) that did not respond to catheter aspiration were treated by tube thoracostomy.

Small pneumothoraces were managed successfully with catheter aspiration in 33 patients (87%) (Table 2). The addition of the Heimlich valve was required for three small pneumothoraces (8%). Tube thoracostomy was required for two small pneumothoraces (5%).

Moderate pneumothoraces were successfully treated with catheter aspiration in 33 patients (60%). The Heimlich valve was required for two moderate pneumothoraces (4%). The addition of pleural suction to the Heimlich valve was successful with four moderate pneumothoraces (7%). Tube thoracostomy was necessary for 16 patients (29%).

Table 2.—Success Rate: Modality vs Size

Modality	No. (%) of Patients				
	Small	Moderate	Large	Unknown	Total
Catheter aspiration	33 (87)	33 (60)	22 (61)	2 (100)	**90** (69)
Heimlich valve	3 (8)	2 (4)	5 (14)	. . .	**10** (8)
Heimlich valve and suction	. .	4 (7)	3 (8)	. . .	**7** (5)
Chest tube	2 (5)	16 (29)	6 (17)	. . .	**24** (18)
Total	**38 (100)**	**55 (100)**	**36 (100)**	**2 (100)**	**131 (100)**

Table 3.—Cost Analysis of the Methods Used for Treatment of Simple Pneumothorax*

Variable	Catheter Aspiration	Heimlich Valve	Heimlich Valve and Suction	Chest Tube or More†
Chest roentgenograms				
Average No. per patient	4.3	6.4	8.3	10.7
Cost each	60	60	60	60
Average cost per patient	258	384	498	642
Emergency department fee	255	255	255	255
Catheter aspiration, Heimlich valve procedure	175	175	175	175

Overall cost per patient	868	2884	3028	6402

*Data are expressed in US dollars.

†The two patients with hemopneumothoraxes following initially successful catheter aspiration are not included.

‡The hospitalization cost is due to four patients who were admitted for other medical reasons.

Large pneumothoraces were managed with catheter aspiration in 22 patients (61%). The addition of the Heimlich valve was necessary in 5 patients (14%). Three large pneumothoraces (8%) required a Heimlich valve placed with pleural suction. Tube thoracostomy was required for six large pneumothoraces (17%).

Two patients with pneumothoraces that initially responded to catheter aspiration, and who were discharged from the emergency department, returned with recurrent pneumothorax. One patient returned within 24 hours and the other patient returned 5 days later. One pneumothorax was a moderate-sized spontaneous pneumothorax, while the other was a small traumatic pneumothorax. Both patients underwent tube thoracostomy and were admitted.

There were three technical complications of catheter aspiration (2.3%), including one hemothorax and two retained sheared catheter tips. The sheared catheter tips were successfully removed by pleuroscopy. All three complications occurred early during the study when an intracatheter technique was used. There were no complications after the Seldinger technique was adopted. No complications occurred from the Heimlich valve or tube thoracostomy.

All emergency department patients who responded to catheter aspiration were managed on an outpatient basis. Patients who required a Heimlich valve with or without suction or tube thoracostomy were admitted. The average length of stay in the hospital per patient was 4.6 days for Heimlich valve therapy, 4.6 days for Heimlich valve with suction, and 11 days for tube thoracostomy. The average cost per patient was $868 for catheter aspiration, $2884 for catheter aspiration with a Heimlich valve, $3028 for catheter aspiration with a Heimlich valve placed on suction, and $6402 for tube thoracostomy (Table 3).

COMMENT

Many therapeutic approaches to simple pneumothorax have been advocated. Simple observation can be used with a small, asymptomatic pneumothorax.[10,11] Other recommended management regimens for larger pneumothoraces have included inpatient simple aspiration, Heimlich valve application, or a Heimlich valve attached to suction.[1-8] Tube thoracostomy, however, has been the "gold standard" for management of simple pneumothorax. While tube thoracostomy is effective for most patients, it is painful and costly, has a complication rate of 3% to 10%, and requires hospitalization.[12,13]

A pilot study from this institution suggested that catheter aspiration for simple pneumothorax is a safe, cost-effective alternative to tube thoracostomy.[6] Initially in our series, catheter aspiration failures were managed with tube thoracostomy. Several reports in the literature suggesting that the use of a Heimlich valve, with or without suction, is a useful adjunct prompted the addition of this modality to our catheter aspiration protocol before resorting to tube thoracostomy.[1,14] In the initial portion of the study (study group 1), 24% of the patients required tube thoracostomy. In the latter portion of the study (study group 2) with the addition of a Heimlich valve, with or without suction for aspiration failures, only 11% required tube thoracostomy. No complications resulted from the use of the Heimlich valve or attachment of the valve to suction. Addition of the Heimlich valve substantially reduced the need for tube thoracostomy in these patients.

Two of the three complications that occurred stemmed directly from the use of an intracatheter (a catheter that slides through a large bore needle). Improper manipulation of the catheter resulted in two sheared and retained catheter tips. In both patients the retained catheter tips were successfully retrieved by pleuroscopy. This complication is similar to those seen when these types of catheters are used for central venous access; removal of the catheter without simultaneous removal of the needle can result in a sheared catheter tip. This complication was eliminated by using the Seldinger technique, which involves advancement of a guide wire through the needle, withdrawing the needle, and advancing the catheter over the guide wire.

Catheter aspiration was most successful with needle-induced and simple traumatic pneumothoraces. Traumatic pneumothoraces that did not respond to catheter aspiration were considered unlikely to respond to Heimlich valve therapy, with or without suction. In these patients, tube thoracostomy was utilized when catheter aspiration failed to adequately expand the lung.

Spontaneous pneumothoraces did not respond to catheter aspiration as well as either needle-induced or traumatic pneumothoraces. In spontaneous pneumothoraces, the failure rate of CASP was 47%. Since many cases of spontaneous pneumothorax involve underlying lung disease, such as apical blebs,

and are associated with persistent air leaks, a higher incidence of CASP failure in this setting is not unexpected.

Small pneumothoraces were readily managed with catheter aspiration. A few studies have advocated conservative management of small pneumothoraces.[10,11] Some of the small pneumothoraces in this study may have been successfully managed by observation. However, all pneumothoraces in this group were symptomatic. Over 85% of the patients with a small pneumothorax were discharged from the emergency department symptom free. This suggests that catheter aspiration does offer some benefit over observation in the management of patients with symptomatic small pneumothoraces.

Moderate and large pneumothoraces responded equally well to catheter aspiration, although not as readily as small pneumothoraces. Pneumothoraces as large as 90% of volume were managed successfully with catheter aspiration. Size of the pneumothorax does not appear to be a determinant of outcome in pneumothoraces that are larger than 20% of volume.

Patient selection is critical for successful use of catheter aspiration. Catheter aspiration is not advised if a hemothorax or pleural effusion is present, if respiratory distress or hemodynamic instability is evident, if the patient has sustained multiple injuries, or if the patient will undergo general anesthesia or require intubation for any reason. As mentioned earlier, use of this technique with spontaneous pneumothorax has a relatively high failure rate, but it is not a contraindication to the use of catheter aspiration since tube thoracostomy can be avoided in approximately 75% of patients with spontaneous pneumothorax.

Substantial cost savings when using catheter aspiration were apparent on analysis. This was true even when the use of the Heimlich valve required hospitalization. Patients requiring tube thoracostomy in this study probably had more resistant pneumothoraces, which necessitated longer hospitalization, ultimately resulting in higher costs. However, in our previous pilot study utilizing matched patients, there was also a clear cost savings with CASP vs tube thoracostomy.[6]

Catheter aspiration, with or without Heimlich valve therapy, appears to be a safe, cost-effective alternative to tube thoracostomy in selected patients with simple pneumothorax. Judicious use of this technique can spare the majority of patients with uncomplicated pneumothorax the pain, morbidity, and expense of tube thoracostomy. Patients who do not respond to catheter aspiration and Heimlich valve therapy can still be managed with conventional tube thoracostomy.

Invited Editorial Comment

This report provokes several comments, all with practical import. The authors do not clearly state the duration of any of these pneumothoraces (up "to several days"). There is a clear relationship between expandability and duration of lesion. This is in accord with the pathologic course of pneumothorax in terms of secretions, atelectatic changes, etc. Were the failed catheters in this group related to delayed therapy? The 11-day hospital stay for patients who underwent tube thoracostomy is difficult to justify. In my experience of some 10 000 tube thoracostomies (*Modern Surgery in South Africa*. 1988;39-47), the average hospital stay was 2.4 days. This group contained 25% simple pneumothoraces, 70% hemopneumothoraces, and 5% simple hemothoraces. These all received physiotherapy and antibiotics. The authors make no mention of these ancillary measures.

Our experience is that a minimum of 24 hours' sustained, stable (no bubbling evident on forceful coughing) expansion is required before removal of the thoracostomy tube. I would not accept the authors' arbitrary 6-hour period as a basis for any therapeutic decision. This may explain the 31% (40 cases) failure rate of CASP in this series. To prove their point, one might suggest repeated CASP for at least a 24-hour period. The pneumothorax may have recurred within 1 hour of the first aspiration!

The authors record that virtually all their patients were symptomatic. Virtually all our patients with smaller pneumothoraces are symptom free. If a patient in this group presents more than 8 hours after the lesion occurs, the patient is discharged and given antibiotics (*Br J Surg*. 1986;73:888-890); the patient's lung expands within about 10 days. When a patient presents less than 8 hours after the lesion occurs, the stability of the pneumothorax is suspect, and the patient receives a tube thoracostomy and the usual full admission to the ward.

I find it difficult to accept the complication rate of 3% to 10% as reported in the literature. Our complication rate remains at a steady 0.4% for all cases. Delius et al report no complications with tubes in their series, which is exactly my point. They do not comment on follow-up: how many symptomatic pneumothoraces recurred?

Practicing as we do here, where money is not a meaningful consideration in patient care, one appreciates the massive average cost of $6500 as estimated for tube thoracostomy. A stay of about 2 days would cut this to approximately $1500 and perhaps induce a reassessment of these protocols. The Heimlich valve is not used in my department, but is superb for the emergency management of battlefield chest injuries before evacuation to a hospital. Transient nonexpansion (continued bubbling into the water seal) occurs in a small percentage of our patients and is managed by suction applied to the outlet of the water seal bottle. These patients have an average hospitalization of 5.5 days.

In conclusion, the authors have not established a management protocol that precludes initial use of a tube thoracostomy. It remains the "gold standard," and it seems hard to justify its nonapplication early on as a routine.

Changing Patterns of Treatment and Survival in Neonates With Meconium Ileus

Frederick J. Rescorla, MD; Jay L. Grosfeld, MD; Karen J. West, MD; Dennis W. Vane, MD

• This report describes 51 neonates with meconium ileus and emphasizes a changing pattern of treatment and improved survival. Twenty-four neonates had uncomplicated meconium ileus due to inspissated meconium obstructing the distal ileum. Twenty-seven neonates had 41 complications of meconium ileus including volvulus (18), bowel atresia (13), perforation (5), and giant cystic meconium peritonitis (5). Nine patients with uncomplicated cases responded to nonoperative clearing of meconium using a meglumine diatrizoate (Gastrografin) enema. Six of 7 patients with enema failures underwent laparotomy, purse-string enterotomy, and intraluminal irrigation. The remaining 9 patients with uncomplicated meconium ileus had resection and enterostomy. Complicated cases were managed by resection and anastomosis (13) or enterostomy (14). Survival at 1 year was 92% in patients with uncomplicated meconium ileus and 85% for those with complicated meconium ileus. Nonoperative Gastrografin enema or enterotomy-irrigation can relieve obstruction in uncomplicated meconium ileus and avoid an enterostomy in most cases.

***(Arch Surg.* 1989;142:837-840**

Cystic fibrosis (CF) is the most common potentially lethal genetic defect affecting the white population. Cystic fibrosis is an inherited autosomal recessive condition that occurs in approximately 1:2000 live births, and is characterized by abnormalities of exocrine gland secretions throughout the body.[1,2] Approximately 6% to 15% of patients with CF present with meconium ileus (MI).[2-4] In this condition, the meconium is extremely viscid, leading to an intraluminal obstruction of the terminal ileum. Approximately one half of these neonates present with a simple uncomplicated obturation intestinal obstruction. The remaining patients present with complications of MI, including volvulus, gangrene, atresia, and perforation, which may result in giant cystic meconium peritonitis. In the past, many neonates with MI were treated by resection of the obstructing bowel segment and formation of an ileostomy fashioned in a variety of techniques. The purpose of this report is (1) to review the current trends in patient management and survival, and (2) to suggest that in uncomplicated cases enterostomy is rarely indicated.

PATIENTS AND METHODS

Fifty-one neonates with MI were treated at the James Whitcomb Riley Hospital for Children, Indiana University Medical Center, Indianapolis, between January 1972 and June 1988. Eighteen patients were female and 33 were male. A family history of CF was present in 6 children. Twenty-four neonates had uncomplicated MI due to obturation obstruction of the distal ileum by concretions of abnormal meconium. Clinical presentation included abdominal distention, bilious vomiting, and failure to pass meconium. Abdominal roentgenographic evaluation demonstrated abdominal distention with variable-sized bowel loops frequently without air-fluid levels. The "soap bubble" sign was often observed in the right middle to lower abdomen (Fig 1). Barium sulfate enema demonstrated an unused microcolon with meconium pellets often observed in the terminal ileum (Fig 2). Ten of these cases presented between 1972 and 1980. Only two (20%) were cleared with a meglumine diatrizoate (Gastrografin, Hypaque) enema, while the remaining 8 neonates required bowel resection, operative irrigation, and formation of an enterostomy. Two neonates had formation of a Bishop-Koop stoma, and 6 had a double-barrel (side-by-side) enterostomy. Of the 14 neonates with uncomplicated MI treated between 1981 and 1988, obstruction was relieved in 7 cases (50%) that were unsuccessfully cleared with a Gastrografin enema (Fig 3). Six of the remaining 7 patients underwent laparotomy, enterotomy through a purse-string suture on the antimesenteric surface of the bowel, and intraoperative irrigation with saline and 25% Hypaque or Gastrografin, which cleared the obstructing meconium (Fig 4). Only one child required an ostomy, which was constructed in a double-barrel fashion. None of the neonates successfully managed by either Gastrografin enema or intraoperative irrigation of the meconium pellets required additional surgical procedures.

Twenty-seven neonates presented with 41 complications of MI, including volvulus in 18, atresia in 13, perforation in 5, and giant cystic meconium peritonitis in 5. Abdominal roentgenograms demonstrated peritoneal calcifications, variable-sized bowel loops, air-fluid levels, and mass effect. Barium enema demonstrated an unused microcolon. Management of neonates with atresia, volvulus, and perforation included resection and anastomosis in 13 neonates and enterostomy in 9. The 5 patients with giant cystic meconium peritonitis underwent evacuation and excision of the pseudocyst and temporary enterostomy. The diagnosis of CF was confirmed by a sweat chloride test in all cases. Patients were placed on pancreatic enzyme therapy and fed routine neonate formula as tolerated. Patients with enterostomy alone and/or complication with enterostomy had a considerably longer hospital stay. Enterostomy closure was usually performed at 6 weeks to 3 months of age.

Survival at 1 year was 92% (22/24) in patients with uncomplicated MI and 85% (23/27) for complicated cases. The mortality was due to pulmonary problems in the uncomplicated cases, and sepsis in two neonates, renal failure in one, and cholestatic liver failure in one in the complicated cases.

COMMENT

In 1905, Landsteiner[5] first described the association of obturator meconium bowel obstruction in the newborn and pathologic changes in the pancreas. Several authors subsequently reported instances of MI with congenital stenosis of

Fig 1.—Abdominal roentgenogram shows small-bowel distention and the "soap bubble" sign (Neuhauser's sign) (arrow), indicating air mixed with meconium.

Fig 2.—Meglumine diatrizoate (Gastrografin) enema demonstrating meconium pellets in the terminal ileum.

the pancreatic ducts.[6,7] In 1936, Fanconi et al[8] described the combination of pancreatic and pulmonary disease of infancy as CF. In 1938, Andersen[9] described the histologic similarities between the pancreatic lesions in CF and MI. The exact origin of the abnormal meconium was initially ascribed to pancreatic achylia.[10] Later studies, however, demonstrated that the severity of the pancreatic disease did not correlate with the occurrence of MI.[11] Abnormal intestinal secretions are currently thought to be the primary causative factor in cases of MI. The diagnosis of CF rests on an elevated sweat chloride test result.

Meconium ileus can be conveniently classified into two forms: uncomplicated cases in which a simple intraluminal obturation ileal obstruction occurs and complicated cases that are related to mechanical complications of the meconium bolus. The heavy meconium-filled segment of bowel just proximal to the narrow obstructed segment filled with intraluminal concentrations may twist, producing a volvulus. The volvulus may result in ischemic necrosis, causing intestinal atresia or perforation with extravasation of meconium into the peritoneal cavity and development of a pseudocyst or giant cystic meconium peritonitis.

Several authors have reported that the diagnosis of fetal meconium peritonitis and MI can be detected on prenatal ultrasound examination.[12,13] As CF is an inherited disorder, prenatal ultrasound examination of high-risk mothers is a reasonable test to perform. Maternal polyhydramnios may be noted in 19% of patients, occurring more commonly in the complicated cases with high obstruction.[14] More commonly, MI presents in a term neonate with abdominal distention, bilious vomiting, and failure to pass meconium. In complicated cases, with pseudocysts or giant cystic meconium peritonitis, patients may have a palpable mass on abdominal examination. A pseudocyst has also been noted to appear as a buttock mass.[15] Cystic fibrosis has been observed in patients with other meconium disorders, including the meconium plug syndrome.[16,17] Ten percent to 12% of neonates born with jejunoileal atresia have CF.[18] These observations indicate that all neonates with intestinal atresia and abnormal meconium presentation (meconium plug syndrome, MI, giant cystic meconium peritonitis, etc) should undergo a sweat chloride test.

Roentgenographic findings in uncomplicated patients usually include a dilated small bowel often without air-fluid levels, due to the fact that the viscosity of the meconium does not allow an interface with the fluid. There may be a soap bubble appearance on plain abdominal roentgenograms (Neuhauser's sign) as a result of meconium mixing with swallowed air.[19] This sign is highly suggestive but not pathognomonic of CF. Complicated cases frequently present with peritoneal calcifications (as a result of perforation and extravasation of meconium into the peritoneum), mass effect (due to volvulus), or air-fluid levels (related to atresia) observed on abdominal roentgenogram.

A barium enema is performed in all cases of low intestinal obstruction in the newborn. This contrast study demonstrates an unused colon (microcolon) and may reveal inspissated meconium pellets within the terminal ileum. In complicated cases, such as atresia, a microcolon with reflux into a decompressed terminal ileum may be noted.

Meconium ileus was generally considered a fatal condition until 1948, when Hiatt and Wilson[20] described a number of survivors following enterotomy and saline irrigation of the obstructing pellets. In 1953, Gross[21] reported successful relief of obstruction following resection and a Mikulicz enterostomy. Olim and Ciuti[22] in 1954 noted that hydrogen peroxide irrigation was useful in aiding the successful evacuation of the inspissated meconium. In 1957, Bishop and Koop[23] described resection and end-to-side anastomosis with a distal ostomy to allow postoperative irrigation. This "chimneylike" stoma (as with the Mikulicz procedure) could be closed by an extraperitoneal operation. In 1961, Santulli and Blanc[24] reported resection with side-to-end anastomosis and proximal ostomy. Meeker and Kincannon[25] in 1964 noted that acetylcysteine irrigation was efficacious in liquifying the obstruction meconi-

Fig 3.—Composite of roentgenograms demonstrating diagnosis and treatment of uncomplicated meconium ileus with a meglumine diatrizoate (Gastrografin) enema. Bottom right, Clearing of Gastrografin and meconium.

um. Holsclaw and associates[26] in 1965 recommended the Bishop-Koop procedure, noting early survival rates of 72% following this operation. Of interest is the fact that these procedures were designed to reduce ileostomy losses and were developed prior to the advent of total parenteral nutrition.

Therapy for MI was altered in 1969 by Noblett's[27] introduction of the Gastrografin enema as a nonoperative form of treatment in uncomplicated cases of MI. Prior to this study, sporadic case reports described patients that had been successfully treated with enemas containing Pancreatin, hydrogen peroxide, and polysorbate 80 (Tween 80) (an industrial detergent).[4,22,27] Noblett described four patients successfully treated with full-strength Gastrografin, a hyperosmolar (1900 mOsm/L) solution of meglumine diatrizoate containing an added wetting agent, polysorbate 80 (0.1% Tween 80). The polysorbate contributes to the effectiveness of the enema by coating the obstructing pellets; however, substances without a wetting agent have also been effective in relieving obstruction. This indicates that the major factor is probably the hyperosmolar nature of Gastrografin, leading to an outpouring of fluid into the bowel lumen and a flushing out of the obstructing meconium pellets.[28] The neonate must be maintained on adequate intravenous fluid infusions throughout the procedure to avoid hypovolemia. A diagnostic barium enema is performed initially. Gastrografin diluted to a 25% to 50% solution is infused into the rectum and colon under fluoroscopic control. Usually, rapid passage of semiliquid meconium occurs over the next 24 to 48 hours. On occasion, a repeated Gastrografin enema may be required. The orogastric tube is removed and diet advanced when the obstruction resolves.

Fig 4.—Illustration demonstrating the technique of enterotomy with insertion of an irrigation catheter through the center of a purse-string suture placed in the antimesenteric surface of the bowel.

The reported success rate of the hypertonic contrast enema varies between 40% to 83%.[29-35] Reviewing a number of reports (since Noblett's original study) over the past two decades, we noted that 56 (58%) of 96 attempted Gastrografin enemas have been successful in relieving the obstruction in cases of uncomplicated MI.[29-35] Complications of the Gastrografin enema have occurred, however, including bowel perforation, hypotension, and necrotizing enterocolitis.[29-37] Perforation of the rectosigmoid is related to catheter trauma, while perforation of the proximal bowel is due to severe overdistention as a result of influx into the bowel. The perforation rate in the above review was 15%. As noted by Noblett[27] in 1969, a Gastrografin enema is contraindicated in the presence of complicating factors such as volvulus, perforation, meconium peritonitis, or atresia.

Surgical treatment of MI continued with Swenson's[38] recommendation in 1962 of resection, irrigation, and end-to-end anastomosis. Few authors have recognized this approach due to concerns of a leak from the anastomosis. In 1970, O'Neill et al[39] reported successful relief of obstruction with tube enterostomy and postoperative irrigation. This technique was later popularized by Harberg et al,[40] who reported successful treatment in 9 of 11 neonates with uncomplicated MI. Kalayoglu et al[14] reported a series of neonates managed by enterotomy and irrigation and considered this procedure a safe alternative in neonates with uncomplicated MI. They used saline, hydrogen peroxide, and acetylcysteine to purge the meconium pellet and concluded that acetylcysteine was probably the most useful irrigant.

Recent reports have supported the safety of intraoperative irrigation and avoidance of an enterostomy. In 1979, Venugopal and Shandling[41] reported successful use of this procedure in 11 of 12 patients with MI. Nguyen et al[33] used acetylcysteine irrigation and a Fogarty catheter to clear the meconium in 6 patients. Caniano and Beaver[34] used diluted acetylcysteine or Gastrografin to clear the meconium in 4 neonates. We currently recommend saline irrigation initially for mechanical separation of the pellets from the bowel wall and evacuation of the meconium. This is followed by instillation of diluted Gastrografin or Hypaque into the proximal bowel and terminal ileum, flushing the solution into the colon to aid in the complete evacuation of the residual meconium.

Gastrografin enema is contraindicated in complicated cases, which are always managed operatively. In cases of

atresia without compromised bowel, our procedure of choice is resection of the dilated atretic segment, distal irrigation, and primary anastomosis.[42] In cases of perforation, volvulus, or giant cystic meconium peritonitis, resection and temporary enterostomy is the preferred procedure.

The operative mortality in patients with CF has decreased considerably over the past three decades. Reports of 50% to 67% mortality rates were common in the 1960s and 1970s.[4,14,26,43] Mabogunje et al,[32] comparing time periods 1942 to 1962 with 1963 to 1980, noted a decrease in overall operative monthly mortality from 52% to 11% and improved survival at 1 year from 23% to 71%. More recent reports (including the present study) confirm the improvement in operative mortality. Caniano and Beaver[34] noted a 100% early survival and 86% late survival in 42 patients with MI. The survival in the current series of 51 cases was 91.6% for uncomplicated MI and 85% for complicated cases at 1 year.

The care of neonates with MI requires a multidisciplinary approach utilizing the expertise of the pediatric pulmonary specialist at an early age in an attempt to optimize the patient's pulmonary status. Parents are carefully instructed and trained to perform percussion and postural drainage and educated regarding the need for dietary enzyme and salt replacement. Genetic consultation should also be offered.

The present study and a recent literature review indicate that in cases of uncomplicated MI, nonoperative treatment with a Gastrografin enema is the initial treatment of choice, with enterotomy and irrigation reserved for cases in which enema fails. Enterostomy can be avoided in most cases. In complicated cases, however, Gastrografin enema is contraindicated. Early surgical intervention is required, and these neonates usually require resection with enterostomy. Although the Mikulicz enterostomy and Bishop-Koop procedure were the most popular methods of stomal formation in the past, both operations were developed prior to the availability of total parenteral nutrition. The Mikulicz clamp is sometimes cumbersome, and the Bishop-Koop procedure requires an intraperitoneal anastomosis often done in the presence of peritonitis. Williams[44] recently noted the occurrence of volvulus if the Bishop-Koop chimney was resected and dropped back into the abdominal cavity. We no longer utilize either of these procedures and currently favor a double-barrel (side-by-side) enterostomy. The neonates are given both enteral nutrition and total parenteral nutritional support, and when in stable condition and in positive nitrogen balance (serum albumin, 32 mg/L; neonate is showing weight gain), the ostomies are closed early (recently, by as early as 4 to 6 weeks). Improved survival is related to early diagnosis, neonatal intensive care unit care, and appropriate nutritional support. Parental education regarding care of the neonate with CF and long-term follow-up is essential.

Medullary Carcinoma in Children

Results of Early Detection and Surgery

Robert L. Telander, MD; Donald Zimmerman, MD; Glen W. Sizemore, MD;
Jon A. van Heerden, MB, ChB; Clive S. Grant, MD

• Early diagnosis and surgical treatment of medullary carcinoma of the thyroid (MCT) in children is essential to decrease the likelihood of metastatic spread. To determine the optimal timing of screening and surgery, we reviewed all children younger than 16 years old who were undergoing surgical treatment. From 1970 to 1988, 33 children 6 months old to 15.9 years old (mean, 9 years old) with MCT or C-cell hyperplasia or both underwent total thyroidectomy. Follow-up was 4 months to 15 years after surgery (mean, 9 years). Six of 31 patients presented with a neck mass. Basal immunoreactive calcitonin level was increased in 3 of 7 patients with C-cell hyperplasia alone, in 10 of 18 patients with nonmetastatic MCT, and in all 5 patients with metastatic MCT. At the time of surgery, 7 patients had C-cell hyperplasia, 19 patients had MCT without metastasis, and 7 patients had MCT with metastases. All children with metastasis were more than 12 years old. Medullary carcinoma of the thyroid was seen as early as age 6 months in a child with multiple endocrine neoplasia type IIb (MEN-IIb) and age 3 years in a child with MEN-IIa. At follow-up, 25 patients were free of disease and 8 had had recurrent disease. Two of the 8 patients with MEN-IIb had died. All 6 children with a neck mass at presentation had recurrent disease. Of 27 patients diagnosed by screening, 25 had no evident disease and 2 had persistent disease. Thus, in children with MEN-II syndromes, screening studies are highly effective in detecting MCT. All children with MEN-IIb should be studied shortly after birth, and those with MEN-IIa should be studied by 1 year old.

***(Arch Surg.* 1989;124:841-843)**

The importance of early diagnosis and surgery for medullary carcinoma of the thyroid (MCT) in children with multiple endocrine neoplasia type II (MEN-II) cannot be overemphasized.[1-5] Only by screening for MCT in very young children can those at risk for MCT be diagnosed prior to metastasis.[3,6] C-cell lesions (C-cell hyperplasia and MCT) synthesize calcitonin as do normal C cells. Patients with MCT may have normal or increased basal immunoreactive calcitonin levels, but agents such as calcium and pentagastrin promote supranormal calcitonin secretion in stimulation tests, thus permitting detection.[7-10] The provocative test to stimulate immunoreactive calcitonin secretion in children with MEN-II and suspected MCT is one of the most successful methods in use for early detection of cancer.[11-13]

It has been found that children can develop both MCT and C-cell hyperplasia at a very early age.[3,6] The optimal time for instituting screening studies, as well as the ideal time for surgery, in very young children is not yet well established. To determine the optimal timing of diagnostic studies and surgical treatment, we evaluated the long-term clinical results of early screening and detection of MCT in children. We elected to review all children under 16 years old who had this diagnosis and who underwent surgical treatment at our institution.

PATIENTS AND METHODS

From 1970 to 1988, 33 children under 16 years old (24 girls and 7 boys) with MCT or C-cell hyperplasia or both were seen and underwent total thyroidectomy. The mean age was 9 years (mean, 0.5 to 15.9 years) (Fig 1). Follow-up ranged from 4 months to 15 years after surgery (mean, 9 years). Plasma immunoreactive calcitonin was measured basally and after pentagastrin infusion, both before and after surgery; anti–human calcitonin antiserum G1701 was used.[13] In addition, all children underwent initial preliminary screening for pheochromocytoma as well as parathyroid disease. Urinary levels of metanephrines, fractionated catecholamines, and vanillylmandelic acid and plasma levels of calcium were determined. When appropriate, immunoreactive parathyroid hormone level was measured.

The surgical procedure consisted of total thyroidectomy with removal of the central zone lymph nodes which extended from the hyoid to the sternal notch and from the midline to the jugular veins. Parathyroid preservation was attempted in all cases. A modified neck dissection with sparing of the sternocleidomastoid muscle was performed if there was evidence of lymph node metastasis.

RESULTS

Except for 1 boy with MEN-IIb for whom the family medical history was uncertain, all children had first-degree relatives with MEN-II. Eight of the 33 children were primary relatives of patients with MEN-IIb and were being studied as part of a family screening. One child with MEN-IIb had no family history of MEN-II. All of the patients with MEN-IIb had MCT and the neuroma phenotype. One had adrenomedullary hyperplasia, and another was found to have clinically

evident pheochromocytoma 7 years after thyroidectomy. Two children with MEN-IIb had feeding difficulties during infancy as well as constipation and diarrhea. Two children had chronic constipation, and 3 children had chronic diarrhea.

The remaining 24 children were similarly at risk because they had relatives with the MEN-IIa syndrome. All but one of the children with MEN-IIa manifested only C-cell disease of the thyroid. The exception was a 12.5-year-old girl with MCT, hyperparathyroidism, and adrenomedullary hyperplasia.

Six of the 33 children presented with a neck mass. On physical examination, palpable nodules were detected in both the thyroid gland and cervical lymph nodes, suggesting metastatic disease in at least 2 of the children with MEN-IIb.

Before surgery, the basal immunoreactive calcitonin level was increased in 3 of 7 patients with C-cell hyperplasia alone, in 10 of 18 patients with nonmetastatic MCT, and in all 5 patients with metastatic MCT (Fig 2). After pentagastrin infusion, immunoreactive calcitonin values were increased in all 29 patients with C-cell disease who underwent the test (Fig 3). Calcium infusion failed to detect C-cell disease in 5 of 18 patients with positive pentagastrin stimulation tests. After thyroidectomy, immunoreactive calcitonin was again measured on at least one occasion and on multiple occasions when indicated.

Of the children who had normal basal but increased stimulated immunoreactive calcitonin values preoperatively, all had normal stimulated values postoperatively. The children with clinical disease consisting of palpable nodules with increased basal immunoreactive calcitonin values had increased immunoreactive calcitonin values postoperatively despite absence of roentgenographically demonstrable distant disease.

During surgery, exploration of the central zone revealed metastatic disease in eight patients. In these children with gross clinical disease, a modified neck dissection sparing the strap muscle and sternocleidomastoid muscle was performed.

At the time of surgery, 7 patients had C-cell hyperplasia alone, 19 patients had MCT without metastasis (15 patients with MEN-IIa, 4 patients with MEN-IIb), and 7 patients had MCT with metastasis (2 patients with MEN-IIa, 5 patients

with MEN-IIb) (Fig 1). All children with metastasis were more than 11.9 years old. Our youngest patient with MCT was 6 months old and had MEN-IIb. Our youngest child with MEN-IIa syndrome and MCT was 2.8 years old. The youngest child with MEN-IIa and C-cell hyperplasia was 1.5 years old.

At follow-up, 25 of the 33 patients were free of disease, 8 had persistent or recurrent disease, and 2 of the 8 patients (both with MEN-IIb) had died (Fig 4). Of the 8 patients with persistent disease, 2 had MEN-IIa syndrome and 6 had MEN-IIb syndrome. The outcome of surgery was related to the manner of presentation. All 6 children with a neck mass at presentation had recurrent disease. Of the 27 patients diagnosed by screening, 25 had no evidence of disease, and 2 had persistent disease.

There were no anesthetic complications, postoperative hemorrhage, injury to the recurrent pharyngeal nerve, or cervical infections. Two children had persistent hypoparathyroidism postoperatively and have been managed on a regimen of vitamin D and calcium.

COMMENT

The detection of occult MCT by measurement of serum immunoreactive calcitonin is one of the truly successful methods of early cancer detection. The reliability of the measurement of immunoreactive calcitonin has been regularly observed. By combining this measurement with pentagastrin infusion in a stimulation test, the method has become even more effective in detecting very early changes in C-cell tissue.[7-10] In patients at risk, it is important to perform pentagastrin stimulation studies as well as basal measurements of immunoreactive calcitonin. We found calcium stimulation less reliable, missing 5 of 18 patients in whom disease was detected by pentagastrin stimulation.

The age at diagnosis of various C-cell lesions varies, but each C-cell lesion may occur at any age. All patients with metastasis found at surgery were 11.9 years old or more. We encountered C-cell hyperplasia in children with MEN-IIa as young as 1.5 years old and MCT at 2.8 years old. Multiple endocrine neoplasia type IIb, which is more aggressive clinically, was associated with C-cell hyperplasia at 15 months old, with MCT at 6 months old, and with MCT with subsequent metastasis at 5.5 years old. This disturbing finding should encourage very early screening. Initial screening in patients at risk for MEN-IIa should begin at 1 year old; in patients at risk for MEN-IIb, it should begin shortly after birth.

Once disease is detected, surgery should be performed because the morbidity may be very low, as in this series of children whose surgeons were accustomed to performing thyroid surgery in young children.

It is clear that optimizing survival requires early detection by screening. We and others have regularly observed that patients presenting with a palpable mass all have persistent disease. It was disturbing to find in this study that, of the eight patients with persistent or recurrent disease, two with MEN-IIa were detected by screening and six had a palpable lesion on presentation. The two patients whose disease was detected by screening were 13 and 14 years old. Thus, detection by screening alone does not guarantee elimination of MCT unless performed at a very young age. The long-term follow-up in this large group of children demonstrates that those patients in whom MCT is detected at a young age, with immunoreactive calcitonin testing, continue to remain free of recurrent MCT.

Risk Management Resources at Your Fingertips

Today, the challenge for physicians and health care institutions to maintain and improve the quality of care is greater than ever. The changing environment of medicine increasingly demands innovative responses from the profession. And, increasingly, physicians and institutions are responding.

The *Compendium of Patient Safety and Medical Risk Management Programs* is a comprehensive listing of patient safety/risk management resources available from the AMA/Specialty Society Medical Liability Project, the American Medical Association, the Council of Medical Specialty Societies, the Physician Insurers Association of America, national medical specialty organizations and state medical associations.

Featuring Capsule Program Descriptions and Complete Index

This is a one-of-a-kind compilation, a uniquely comprehensive guide to such resources as:

Guidelines and policy statements · Committee and task force activities · Courses and seminars · Self-assessment programs · Data banks · Research projects · Publications, from manuals and books to newsletters and pamphlets · Clearinghouses, resource centers, bibliographies · Videotapes, audiotapes, slide programs

Instructions for Authors

Manuscripts are to be sent by first-class mail to the Editor, Claude H. Organ, Jr, MD, Professor, Dept of Surgery, University of California–Davis, East Bay 1411 E 31st St, Oakland, CA 94602. The procedures listed must be followed carefully and all materials requested must be enclosed for prompt review and consideration for publication in the *Archives of Surgery.* Use the checklist to ensure completeness.

Manuscript Preparation.—*The original typescript and two high-quality copies* of the entire manuscript must be submitted, including copies of all illustrations, legends, tables, and references. All copy, including references, legends, and tables, must be typed double-spaced on 8½ × 11-in, heavy-duty white bond paper. Margins must be at least 1 in. If a word processor is used, do *not* use justified right margins.

Abstract.—*Submit an abstract* (135-word maximum) of the manuscript, which must include a statement of the problem, methods of study, results, and conclusions. The synopsis-abstract replaces a summary or conclusions.

Copyright.—*A copyright release* form signed by *all* authors of manuscripts, brief communications, and correspondence is required by the Copyright Revision Act of 1976. The following statement, dated and signed by all authors, may be used: **"In consideration of the American Medical Association's taking action in reviewing and editing my submission, the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the AMA in the event that such work is published by the AMA."**

Financial Interest.—List all affiliations with or financial involvement in any organization or entity with a direct financial interest in the subject matter or materials of the research discussed in the manuscript (eg, employment, consultancies, stock ownership). All such information will be held in confidence during the review process. Should the manuscript be accepted, the Editor will discuss with the author the extent of disclosure appropriate for publication.

References.—*References* should be listed in *consecutive numerical order* as they are cited in the text, *not alphabetically.* Once a reference is cited, all subsequent citations should be to the original number. All references must be cited in the text or tables. Unpublished data and personal communication may not be listed as references. References to journal articles should include (1) authors, (2) title, (3) journal name as abbreviated in *Index Medicus,* (4) year, (5) volume number, and (6) inclusive page numbers—in that order. References to books should include (1) authors, (2) chapter title, if any, (3) editor, if any, (4) title of book, (5) year, (6) city, and (7) publisher. Volume and edition numbers, specific pages, and name of translator should be included when appropriate. **The author is responsible for the accuracy and completeness of the references and for their correct text citation.**

Author Responsibility.—One author must be designated *corresponding author,* with his or her address and telephone number provided. All correspondence and copy editing are sent to this author. The corresponding author will receive an edited typescript rather than galley proofs for approval. The authors are responsible for all statements in their work, including changes made by the copy editor. Order reprints at the time the typescript is returned after editorial processing. Specify the address to which requests for reprints should be sent.

Titles.—*The title* must be *short,* specific, and clear. It cannot exceed 42 characters per line, including punctuation and spaces, and is limited to two lines. The title page should include the full names and academic affiliations of all authors. If the manuscript was presented at a meeting, indicate the name of the organization, the place, and the date on which it was read.

SI Units.—Use Système International (SI) measurements throughout the manuscript.

Illustrations.—Use only illustrations that clarify and augment the text. Submit illustrations in triplicate, unmounted and untrimmed. Do not send original artwork. Send high-contrast glossy prints (not photocopies). Figure number, name of senior author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. All lettering must be legible after reduction to column size. Artwork submitted for publication may be relettered to achieve uniformity of lettering style throughout the journal. Illustrations should preferably be in a proportion of 5 × 7 in. *Color illustrations* are accepted for publication if the editors believe that color will add significantly to the published manuscript. The ARCHIVES will pay only part of the expense of color reproduction and printing color illustrations. The author's share of the expense is $400 for up to six square finished illustratons that can be arranged on a one-page layout. Any additional illustrations or special effects will be billed to the author at cost. Positive color transparencies (35-mm preferred) must be submitted for an evaluation. Do not send color prints unless accompanied by original transparencies.

CHECKLIST FOR AUTHORS

Send:

- Three copies of manuscript.
- Three copies of synopsis-abstract.
- Three copies of attached photographs, legends, tables, and/or illustrations clearly marked as described in the instructions.
- A copyright release statement signed by *all* authors.
- The address and telephone number of the designated corresponding author.
- Send to Claude H. Organ, Jr, MD
  Archives of Surgery
  Professor, Dept. of Surgery
  University of California–Davis, East Bay
  1411 E 31st St
  Oakland, CA 94602
- Use sufficient postage.

(Continued on p 846.)

(Continued from p 845.)

Legends.—*Legends* must be typed double-spaced, beginning on a separate sheet of paper. Length is limited to a maximum of 40 words.

Tables.—Each table must be typed double-spaced, including all headings, on a separate sheet of 8½ × 11-in paper. Do not use larger-size paper. If a table must be continued, use a second sheet and repeat all heads and stubs. Each table must have a title.

Manuscript Acceptance.—Manuscripts are received with the understanding that they *are not* under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the ARCHIVES and may not be published elsewhere without permission from the publisher (AMA).

OTHER INFORMATION

Brief Clinical Notes.—The ARCHIVES welcomes the submission of Brief Clinical Notes for review. These are generally reports of cases that provide a new or unique contribution and are to consist of no more than 400 words, two references, and one illustration. The synopsis-abstract may not exceed 80 words.

Correspondence and Brief Communications.—The Editor is pleased to receive letters that pertain to material published in the ARCHIVES as well as brief communications concerning other matters of interest to our readers. An interesting case may be published as a brief communication. Such contributions should be 250 words or less, typewritten, double-spaced without an abstract, and clearly marked "for publication." No more than two references are permitted and illustrations or tables are acceptable only when essential to the message.

News and Announcements.—Brief notices may be submitted of meetings, seminars, or symposiums that are of interest to surgeons.

Acknowledgments.—Illustrations from other publications must be acknowledged. Include the following when applicable: authors, title of article, title of journal or book, volume number, pages, month and year. The publisher's permission to reprint must be submitted to the ARCHIVES when the manuscript has been formally accepted.

Statistical Review.—Manuscripts containing statistical evaluation should include the name and affiliation of the statistical reviewer.

Informed Consent.—Manuscripts reporting the results of experimental investigations on human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure(s) had been fully explained.

Reference to Patients.—Patients should be referred to by number or, in anecdotal reports, by fictitious given names. Real names or initials must not be used in the text, tables, or illustrations.

Photographic Consents.—A letter of consent must accompany all photographs of patients in which a possibility of identification exists. It is *not* sufficient to simply cover the eyes to mask identity.

AMA Manual of Style.—This 1988 edition, formerly the *Manual for Authors & Editors*, is available from Williams & Wilkins, 428 E Preston St, Baltimore, MD 21202. Single copy price: $24.95. A shipping charge is added on all orders not prepaid. If additional ordering information is needed, or to order by telephone, call 1-800-638-0672.

Evaluation of Staging Workup in Malignant Melanoma

Tawfiq Khansur, MD; Jane Sanders, MD; Suman K. Das, MD

• To evaluate the role of staging workup in primary and recurrent malignant melanoma, we reviewed the results in 115 patients with primary melanoma and in 28 patients with recurrent disease who underwent evaluation with chest roentgenograms, radionuclide bone and liver scans, and either a radionuclide brain scan or computed tomography of the brain. Upper gastrointestinal tract series with small-bowel follow-through were obtained in 42 patients. Metastatic disease was documented in nine of 143 chest roentgenograms, seven of 137 liver-spleen scans, three of 141 bone scans, two of 85 brain scans, two of 43 brain computed tomographic scans, and two of 42 upper gastrointestinal tract series. All documented metastasis was in stage II and recurrent melanoma. Postoperatively determined serum lactate dehydrogenase levels showed greater than 300 U/L in all patients with documented metastasis except in two with bone and one with brain metastases. We conclude that, in view of low yield, there is no role for routine metastatic workup to detect silent metastasis in malignant melanoma. Elevated postoperative serum lactate dehydrogenase levels indicate need for metastatic workup.
(*Arch Surg* 1989;124:847-849)

Malignant melanoma is ubiquitous and unpredictable in metastatic potential.[1,2] A significant incidence of systemic relapse after radical surgery is seen within five years in stage I and II melanoma,[3,4] and systemic disease is universal after resection in local and regional recurrence,[5] suggesting occult micrometastasis at diagnosis. Clinically unsuspected metastases have been noted in the central nervous system and other sites at autopsy.[6,7] Metastatic disease has a predilection for lung, liver, bone, central nervous system, and the gastrointestinal tract, and melanoma has been found at autopsy in most organs. In view of this aggressive metastatic potential, staging workup is often advocated to exclude silent metastasis and as a baseline for future reference.[8]

Radionuclide bone scan and computed tomography (CT) of the brain detect early asymptomatic metastases in breast and lung cancer, respectively.[9,10] Preoperative screening workup in these tumors obviates the need for unnecessary surgery. Staging in malignant melanoma has been explored only in stage I disease, in bone and liver.[11,12]

We conducted this study to evaluate the role of metastatic workup in stage I and II melanoma and in local and regional recurrence. Our results failed to justify routine evaluation for metastasis in liver, brain, bone, and bowels. These tests are best individualized on the basis of clinical symptoms and laboratory indications suggesting metastasis. We also found that elevated postoperative serum lactate dehydrogenase (LDH) level is a useful marker of residual or metastatic disease.

PATIENTS AND METHODS

We reviewed the metastatic evaluation of all patients with malignant melanoma seen at the University Hospital and the Veterans Administration Hospital, Jackson, Miss, over a 12-year period from 1975 to 1987. All patients had their workups after resection of primary or recurrent melanoma or in the immediate postoperative period, ranging from one to eight weeks after resection performed at an outside hospital. The histologic diagnosis of melanoma was confirmed in all patients by our hospital pathologists.

There were 163 patients with the diagnosis of malignant melanoma in skin. Melanomas of mucous membrane and uveal tract were excluded. All patients were grouped by stage after clinicopathologic evaluation; 72 had stage I disease, 54 had stage II, and 28 had local and regional recurrence of melanoma. Nine patients could not be assigned to a stage. Of these, 143 were found to have undergone at least three of the following evaluations: radionuclide brain, bone, and liver scan, CT of the head, and upper gastrointestinal tract series with small-bowel follow-through. These 143 patients are the subject of our evaluation. All patients had posteroanterior and lateral chest roentgenograms, liver function tests (alkaline phosphatase, aspartate aminotransferase, and γ-glutamyl transpeptidase), and serum LDH determinations.

All radionuclide imaging was done with a gamma camera. Bone scans were obtained in 141 patients two to three hours after a dose of technetium Tc 99m methylene diphosphonate. Positive bone scans were confirmed with skeletal roentgenograms. Liver-spleen scans were done in 137 patients 15 to 20 minutes after injection of technetium Tc 99m sulfur colloid. Equivocal and positive scans were confirmed with ultrasound and/or CT of the liver. Histologic confirmation was obtained whenever possible. Brain scanning was performed in 85 patients three to four hours after injection of technetium Tc 99m sodium pertechnetate.

Accepted for publication Sept 1, 1988.

Table 1.—Chest Roentgenograms

Finding	No. of Patients	Stage	Serum LDH, U/L*	Final Diagnosis in Lung
Solitary nodules (n = 5)	3	II	>300	Melanoma (n = 2), lung cancer (n = 1)
	2	I	Normal	Benign
Multiple nodules (n = 2)	1	I	>300	Melanoma
	1	Recurrent	>300	Melanoma
Pleural effusion (n = 2)	1	Recurrent	>300	Melanoma
	1	I	Normal	Benign effusion
Hilar mass (n = 1)	1	II	>300	Melanoma
Mediastinal widening (n = 1)	1	Recurrent	>300	Melanoma
Interstitial pattern (n = 1)	1	II	>300	Melanoma

*LDH indicates lactate dehydrogenase.

Table 2.—Liver-Spleen Scan

Finding	Stage	Serum LDH, U/L*	Serum Alkaline Phosphatase	Final Diagnosis in Liver
Solitary defect (n = 5)	I (n = 2)	Normal (n = 4)	Normal	False positive
	II (n = 3)	300 (n = 1)	Elevated	Melanoma
Multiple defect (n = 2)	II	>300	Elevated	Melanoma
Diffuse abnormalities (n = 3)	II (n = 2) Recurrent (n = 1)	>300 (n = 3)	Elevated	Melanoma (n = 2) Cirrhosis (n = 1)
Splenomegaly (n = 5)	II (n = 3)	>300 (n = 5)	Elevated (n = 1) Normal (n = 2)	Melanoma (n = 2) Chronic granulocytic leukemia (n = 1)
	I (n = 2)	. . .	Normal (n = 2)	Autoimmune hemolytic anemia (n = 1) Unknown (n = 1)

*LDH indicates lactate dehydrogenase.

Positive and equivocal scans were confirmed by CT. Forty-three patients had CT as the screening workup for brain metastasis. These were performed with contrast materials.

Upper gastrointestinal tract series with small-bowel follow-through were obtained in 43 patients. Serum LDH determinations and liver function tests were performed on all patients, and the values evaluated are postoperative levels. Normal serum LDH level for our laboratory ranges from 100 to 205 U/L.

RESULTS

Twelve of 143 chest roentgenograms had abnormalities. These included solitary nodules in five, multiple nodules in two, pleural effusion in two, and hilar mass, mediastinal widening, and interstitial pattern in one each. The results after workup and correlation with serum LDH level and stage of disease are shown in Table 1. All true-positive chest roentgenograms were seen in stage II and recurrent melanoma. Serum LDH level was evaluated in all true-positive cases as well as in the patient with lung cancer.

Fifteen of 137 liver scans showed photon defects, either equivocal for, suggestive of, or definitive for metastases. This consisted of solitary photon defects in five, multiple defects in two, diffuse abnormalities in three, and splenomegaly in five. The results of further workup with ultrasound, CT, biopsy, or laparotomy are shown in Table 2. The serum LDH levels and liver function tests and stages of disease are also related. The LDH level was elevated in all patients with true-positive scans and in those with splenomegaly associated with chronic granulocytic leukemia and hemolytic anemia.

Bone scan abnormalities were seen in 12 of 141 scans. These consisted of solitary lesions in eight patients and multiple abnormalities in four. Skeletal roentgenograms confirmed metastases in three (one with solitary and two with multiple lesions). Nine (seven solitary and two with multiple lesions) proved to be false positive. Skeletal roentgenograms were normal, follow-up scans normalized in seven, and biopsy findings were normal in two. Serum LDH level was greater than 300 U/L in one of three patients with true-positive scans and normal in the rest. Serum alkaline phosphatase level was elevated in two of three patients with true-positive scans and within normal limits in those with false-positive scans. Bone pain did not correlate with true-positive scans.

Three of 85 radionuclide brain scans were positive; of these, two were confirmed with CT scans. Two of 43 CT scans of brain obtained as primary evaluation workup were positive. Serum LDH level was greater than 300 U/L in three of the four patients with brain metastasis. Three of the four were symptomatic and one was asymptomatic. The asymptomatic patient had an LDH level of greater than 300 U/L. Two of 43 upper gastrointestinal tract series with small-bowel follow-through were positive. One patient had gastrointestinal tract symptoms, and serum LDH level was elevated in both. Metastatic melanoma in the bowel was found at laparotomy in one and at autopsy in the second patient.

COMMENT

Previous studies have attempted to define the value of preoperative roentgenograms and scans in stage I melanoma.[11,12] Our results with systemic staging for metastatic disease in stages I and II and local-regional recurrence for melanoma proved unrewarding. A battery of radionuclide scans of brain, liver, and bone, CT of brain, and gastrointestinal tract series showed a positive yield in a rare patient in the absence of symptoms and laboratory evidence. Metastatic disease was seen in none of the 72 patients with stage I disease. There were, however, two false-positive

chest roentgenograms, four false-positive liver-spleen scans, and three false-positive bone scans associated with stage I disease. Although metastatic disease was detected in stage II and recurrent melanoma, only one patient with central nervous system metastasis, one with bone metastasis, one with gastrointestinal tract metastasis, and two with splenic metastases were detected when free of symptoms and with normal results of liver function tests. Furthermore, both liver and bone scans showed a significant false-positive rate. We, however, found nine of 143 chest roentgenograms to be positive, and eight were in asymptomatic patients. A chest roentgenogram should be obtained in all patients, although the yield is low.

Serum LDH level has been shown to be a sensitive marker for hepatic metastasis.[13] We found serum LDH levels of greater than 300 U/L in all patients with true-positive liver-spleen scans as well as in those with chest and bowel disease. An LDH level of greater than 300 U/L was also seen in two of three patients with brain metastases and in one of three with bone metastases. In 121 other patients, a serum LDH level of greater than 300 U/L was observed in seven patients, of whom one had chronic granulocytic leukemia, another autoimmune hemolytic anemia, and two metastatic melanoma within six months of follow-up (one in the liver and another in subcutaneous tissue). In three others, the cause for an elevated serum LDH level of greater than 300 U/L was not clear. A serum LDH level of greater than 205 U/L (upper limits of normal) but less than 300 U/L was seen in six patients. Two proved to have metastases within six months, one with liver and the second with lung and liver metastasis. Our data suggest that LDH level is a marker of tumor burden at a number of sites besides liver, and that there is a possible role for postoperative serum LDH level in identifying the rare patient with silent metastasis.

We conclude that there is no role for routine evaluation with radionuclide liver, bone, and brain scans, CT of brain, and upper gastrointestinal tract series with small-bowel series in patients with stage I and II melanoma, as well as in local and regional recurrence of melanoma. Such a workup should be dictated by symptoms and laboratory evidence for possible metastasis. A serum LDH level of greater than 300 U/L should prompt the search for the rare patient with asymptomatic metastasis.

DEFINING A NEW STANDA

RD FOR EMPIRIC THERAPY

For Infection Following
Complicated Abdominal Surgery

BETTER THAN AMINOGLYCOSIDE COMBINATIONS FOR MOST PATIENTS

For These Reasons...

- ☐ Gram-negative coverage of an aminoglycoside plus
- ☐ Gram-positive coverage of cefazolin plus
- ☐ Anaerobic coverage of clindamycin or metronidazole plus
- ☐ Enterococcal coverage of ampicillin plus
- ☐ Tolerability profile characteristic of beta-lactam antibiotics

...PRIMAXIN Is a Better Choice for Empiric Therapy

Coverage of specified agents is based upon the Microbiology Section of the Prescribing Information as published in the 1988 *Physicians' Desk Reference*®

Data available from Merck Sharp & Dohme, West Point, PA 19486.

PRIMAXIN is contraindicated in patients who have shown hypersensitivity to any component of this product. Before initiating therapy with PRIMAXIN, careful inquiry should be made concerning previous hypersensitivity reactions to penicillins, cephalosporins, other beta-lactams, and other allergens. If an allergic reaction to PRIMAXIN occurs, discontinue the drug. Serious hypersensitivity reactions may require epinephrine and other emergency measures.

In vitro activity does not necessarily imply *in vivo* effectiveness.

*when indicated organisms are suspected at indicated sites

INTRAVENOUS

PRIMAXIN®

(Imipenem-Cilastatin Sodium/MSD)

Please see Brief Summary of Prescribing Information on following page.

Copyright © 1988 by Merck & Co., Inc.

INTRAVENOUS

PRIMAXIN®

(Imipenem-Cilastatin Sodium/MSD)

Contraindications: PRIMAXIN is contraindicated in patients who have shown hypersensitivity to any component of this product.

Warnings: SERIOUS AND OCCASIONALLY FATAL HYPERSENSITIVITY (anaphylactic) REACTIONS HAVE BEEN REPORTED IN PATIENTS RECEIVING THERAPY WITH BETA LACTAMS. THESE REACTIONS ARE MORE APT TO OCCUR IN PERSONS WITH A HISTORY OF SENSITIVITY TO MULTIPLE ALLERGENS.

THERE HAVE BEEN REPORTS OF PATIENTS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY WHO HAVE EXPERIENCED SEVERE HYPERSENSITIVITY REACTIONS WHEN TREATED WITH ANOTHER BETA LACTAM. BEFORE INITIATING THERAPY WITH 'PRIMAXIN,' CAREFUL INQUIRY SHOULD BE MADE CONCERNING PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, OTHER BETA LACTAMS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION TO 'PRIMAXIN' OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis has been reported with virtually all antibiotics, including PRIMAXIN; therefore it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use. This colitis may range in severity from mild to life threatening.

Mild cases of pseudomembranous colitis may respond to drug discontinuance alone. In more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte, and protein supplementation, and the use of a drug such as oral vancomycin, as indicated. Isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—CNS adverse experiences such as confusional states, myoclonic activity, and seizures have been reported during treatment with PRIMAXIN, especially when recommended dosages were exceeded. These experiences have occurred most commonly in patients with CNS disorders (e.g., brain lesions or history of seizures) and/or compromised renal function. However, there have been reports of CNS adverse experiences in patients who had no recognized or documented underlying CNS disorder or compromised renal function.

Patients with severe or marked impairment of renal function, whether or not undergoing hemodialysis, had a higher risk of seizure activity when receiving maximum recommended doses than those with no impairment of renal function; therefore, maximum recommended doses should be used only where clearly indicated (see DOSAGE AND ADMINISTRATION).

Patients with creatinine clearances of ≤5 mL/min/1.73 m² should not receive PRIMAXIN unless hemodialysis is instituted within 48 hours.

For patients on hemodialysis, PRIMAXIN is recommended only when the benefit outweighs the potential risk of seizures.

Close adherence to the recommended dosage and dosage schedules is urged, especially in patients with known factors that predispose to convulsive activity. Anticonvulsant therapy should be continued in patients with known seizure disorders. If focal tremors, myoclonus, or seizures occur, patients should be evaluated neurologically, placed on anticonvulsant therapy if not already instituted, and the dosage of PRIMAXIN re-examined to determine whether it should be decreased or the antibiotic discontinued.

As with other antibiotics, prolonged use of PRIMAXIN may result in overgrowth of nonsusceptible organisms. Repeated evaluation of the patient's condition is essential. If superinfection occurs during therapy, appropriate measures should be taken. While PRIMAXIN possesses the characteristic low toxicity of the beta-lactam group of antibiotics, periodic assessment of organ system function during prolonged therapy is advisable.

Drug Interactions—Since concomitant administration of PRIMAXIN and probenecid results in only minimal increases in plasma levels of imipenem and plasma half-life, it is not recommended that probenecid be given with PRIMAXIN.

PRIMAXIN should not be mixed with or physically added to other antibiotics. However, PRIMAXIN may be administered concomitantly with other antibiotics, such as aminoglycosides.

Carcinogenesis, Mutagenesis, Impairment of Fertility—Gene toxicity studies were performed in a variety of bacterial and mammalian tests *in vivo* and *in vitro*. The tests were: V79 mammalian cell mutation assay (PRIMAXIN alone and imipenem alone), Ames test (cilastatin sodium alone), unscheduled DNA synthesis assay (PRIMAXIN), and *in vivo* mouse cytogenicity test (PRIMAXIN). None of these tests showed any evidence of genetic damage.

Reproduction tests in male and female rats were performed with PRIMAXIN at dosage levels up to 8 times the usual human dose. Slight decreases in live fetal body weight were restricted to the highest dosage level. No other adverse effects were observed on fertility, reproductive performance, fetal viability, growth, or postnatal development of pups. Similarly, no adverse effects on the fetus or on lactation were observed when PRIMAXIN was administered to rats late in gestation.

Pregnancy—Pregnancy Category C: Teratogenicity studies with cilastatin sodium in rabbits and rats at 10 and 33 times the usual human dose, respectively, showed no evidence of adverse effect on the fetus. No evidence of teratogenicity or adverse effect on postnatal growth or behavior was observed in rats given imipenem at dosage levels up to 30 times the usual human dose. Similarly, no evidence of adverse effect on the fetus was observed in teratology studies in rabbits with imipenem at dosage levels at the usual human dose.

Teratology studies with PRIMAXIN at doses up to 11 times the usual human dose in pregnant mice and rats during the period of major organogenesis revealed no evidence of teratogenicity.

Data from preliminary studies suggest an apparent intolerance to PRIMAXIN (including emesis, inappetence, body weight loss, diarrhea, and death) at doses equivalent to the average human dose in pregnant rabbits and cynomolgus monkeys that is not seen in nonpregnant animals in these or other species. In other studies, PRIMAXIN was well tolerated in equivalent or higher doses (up to 11 times the average human dose) in pregnant rats and mice. Further studies are under way to evaluate these findings.

There are, however, no adequate and well-controlled studies in pregnant women. PRIMAXIN should be used only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers—It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when PRIMAXIN is administered to a nursing woman.

Pediatric Use—Safety and effectiveness in infants and children below 12 years of age have not yet been established.

Adverse Reactions: PRIMAXIN is generally well tolerated. Many of the 1,723 patients treated in clinical trials were severely ill and had multiple background diseases and physiological impairments, making it difficult to determine causal relationship of adverse experiences to therapy with PRIMAXIN.

Local Adverse Reactions—Local adverse clinical reactions that were reported as possibly, probably, or definitely related to therapy with PRIMAXIN were: phlebitis/thrombophlebitis (3.1%), pain at the injection site (0.7%), erythema at the injection site (0.4%), vein induration (0.2%), infused vein infection (0.1%).

Systemic Adverse Reactions—The most frequently reported systemic adverse clinical reactions that were reported as possibly, probably, or definitely related to PRIMAXIN were: nausea (2.0%), diarrhea (1.8%), vomiting (1.5%), rash (0.9%), fever (0.5%), hypotension (0.4%), seizures (0.4%) (see PRECAUTIONS), dizziness (0.3%), pruritus (0.3%), urticaria (0.2%), somnolence (0.2%).

Additional adverse systemic clinical reactions reported as possibly, probably, or definitely drug related occurring in less than 0.2% of the patients or reported since the drug was marketed are listed within each body system in order of decreasing severity: *Gastrointestinal*—pseudomembranous colitis (see WARNINGS), hemorrhagic colitis, hepatitis (rarely), gastroenteritis, abdominal pain, glossitis, tongue papillar hypertrophy, heartburn, pharyngeal pain, increased salivation; *CNS*—encephalopathy, tremor, confusion, myoclonus, paresthesia, vertigo, headache, psychic disturbances; *Special Senses*—transient hearing loss in patients with impaired hearing, tinnitus, taste perversion; *Respiratory*—chest discomfort, dyspnea, hyperventilation, thoracic spine pain; *Cardiovascular*—palpitations, tachycardia; *Skin*—toxic epidermal necrolysis (rarely), erythema multiforme, facial edema, flushing, cyanosis, hyperhidrosis, skin texture changes, candidiasis, pruritus vulvae; *Body as a Whole*—polyarthralgia, asthenia/weakness; *Renal*—acute renal failure (rarely), oliguria/anuria, polyuria. The role of PRIMAXIN in changes in renal function is difficult to assess, since factors predisposing to prerenal azotemia or to impaired renal function usually have been present.

Adverse Laboratory Changes—Adverse laboratory changes without regard to drug relationship that were reported during clinical trials or reported since the drug was marketed were: *Hepatic*—increased SGPT, SGOT, alkaline phosphatase, bilirubin, and LDH; *Hemic*—increased eosinophils, positive Coombs test, decreased WBC and neutrophils, including agranulocytosis, increased WBC, increased platelets, decreased platelets, decreased hemoglobin and hematocrit, increased monocytes, abnormal prothrombin time, increased lymphocytes, increased basophils; *Electrolytes*—decreased serum sodium, increased potassium, increased chloride; *Renal*—increased BUN, creatinine; *Urinalysis*—presence of urine protein, urine red blood cells, urine white blood cells, urine casts, urine bilirubin, and urine urobilinogen.

NOTE: Due to the high antimicrobial activity of PRIMAXIN, it is recommended that the maximum total daily dosage not exceed 50 mg/kg/day or 4.0 g/day, whichever is lower.

How Supplied: PRIMAXIN is supplied as a sterile powder mixture in vials, infusion bottles, and single-dose ADD-Vantage*† vials containing imipenem anhydrous and cilastatin sodium as follows: 250 mg imipenem equivalent and 250 mg cilastatin equivalent; 500 mg imipenem equivalent and 500 mg cilastatin equivalent.

Caution: The suspension from vials is not for direct infusion.

Early Detection of Shock in Critically Ill Patients by Skeletal Muscle Po_2 Assessment

Gerard I. J. M. Beerthuizen, MD; R. Jan A. Goris, MD; Ferdinand J. A. Kreuzer, PhD

• The usefulness of skeletal muscle Po_2 assessment in monitoring patients at risk of shock was evaluated in 20 critically ill patients. A shock score, inotropic score, and combined inotropic-shock score were calculated. If the median skeletal muscle Po_2 assessment was more than 31.5 mm Hg, no shock occurred in the period from 4 hours before to 6 hours after the measurement. The risk of shock occurring during the first 2 hours after the skeletal muscle Po_2 assessment was 2.2 times higher if median skeletal muscle Po_2 assessment was below 22.5 mm Hg. If inotropes were administered, no significant difference was found in the incidence of shock if skeletal muscle Po_2 was below or above 22.5 mm Hg. Skeletal muscle Po_2 assessment enables the determination of the severity of shock and determination of risk of shock in critically ill patients, provided no treatment with inotropes has been instituted.

(*Arch Surg.* 1989;124:853-855)

Oxygen is the most flow limited of all substances necessary for metabolism. The oxygen transport system thus is of vital importance for the integrity of cellular metabolism. However, one or more of the several components of the oxygen transport system may function abnormally in critical illness.[1-3]

Inadequate tissue perfusion and oxygenation are the early common physiologic denominators of shock,[4-8] but shock is usually not diagnosed before there is a significant and persistent fall in the systolic arterial blood pressure. Direct estimation of tissue perfusion in patients is not yet possible, but skeletal muscle Po_2 might provide an indicator of the adequacy of the peripheral circulation.

This study evaluates the usefulness of skeletal muscle Po_2 assessment in monitoring patients at risk of shock. Critically ill patients were studied to establish whether skeletal muscle Po_2 assessment could detect developing shock in an early stage and whether skeletal muscle Po_2 assessment could predict the risk of shock during a period after the skeletal muscle Po_2 assessment.

PATIENTS AND METHODS

Patients admitted to the study conformed to one of these entry criteria: for imminent shock: urinary output less than 0.5 mL/kg per hour, heart rate greater than 120 beats per minute, decrease in systolic arterial blood pressure of 30 mm Hg or more, respiratory rate greater than 30/min in the absence of pulmonary disease, and temperature of 39°C or more; for shock: systolic arterial blood pressure less than 90 mm Hg; and inotropes given for treatment of shock. The experimental protocol was approved by the institutional review board. Informed consent was obtained from all patients or their relatives. Treatment of the patients was not influenced by their admission to the study.

The result of the skeletal muscle Po_2 assessment did not change the treatment instituted. Measurements were performed according to a fixed protocol. Heart rate, arterial blood pressure, central venous pressure, core temperature, arterial Po_2, arterial Pco_2, arterial pH, arterial bicarbonate level, and arterial base excess were determined, and urinary output per hour and amount of intravenous fluids were recorded. Skeletal muscle Po_2 was assessed in the quadriceps femoris muscle by means of a polarographic needle electrode.[9] The electrode was calibrated before the measurement and positioned in the vastus lateralis of the quadriceps femoris muscle approximately 3 to 4 cm deep, with a 20-gauge needle used as a guiding cannula. The electrode was withdrawn stepwise. After each step of 200 μm, a Po_2 value was measured. In this way, 100 Po_2 values from 100 different places in the skeletal muscle were obtained. From these 100 Po_2 values, the median, representing the skeletal muscle Po_2 assessment, was calculated. After each assessment, the electrode was withdrawn from the patient. One complete skeletal muscle Po_2 assessment took 5 minutes. Measurements were performed on entry into the study and repeated 2, 4, 6, 8, and 16 hours later.

To determine the amount of inotropes administered and the severity of shock, we developed an inotropic score and a shock score. For each period, the presence of shock was registered by means of the shock score—0 indicates maintenance of systolic arterial blood pressure above 90 mm Hg without additional measures; 1, maintenance of systolic arterial blood pressure above 90 mm Hg by additional infusion of plasma expanders, increasing the amount of inotropes, and/or urinary output less than 0.5 mL/kg per hour (if the patient showed no preexisting terminal renal failure); 2, systolic arterial blood pressure less than 90 mm Hg; and 3, systolic arterial blood pressure less than 80 mm Hg. The most severe event occurring during one period determined the shock score. The dose of administered inotropes was recorded, and an inotropic score was determined—1, no inotropes; 2, dopamine hydrochloride or dobutamine hydrochloride, less than 20 mg/h; 3, dopamine hydrochloride or dobutamine hydrochloride, more than 20 mg/h; and 4, epinephrine. The lower dose of dopamine was often used to improve diuresis. The higher dose of dopamine or dobutamine was always used initially to increase arterial blood pressure; if this failed, epinephrine was added.

In some patients, shock occurred when inotropic drugs were not administered; in other patients, inotropic drug treatment had already been instituted. For this reason, the severity of the circulatory failure was also estimated by a combined inotropic and shock score. This score combined the inotropic treatment and the events before and after skeletal muscle Po_2 assessment: combined score = (maximal shock score 2 hours after measurement of Po_2) + (0.5 × maximal shock score 2 hours before measurement of Po_2) + (inotropic score at time of measurement of Po_2).

The results were analyzed statistically by means of the Fisher Exact Test for 2 × 2 tables.

RESULTS

The study was performed in 20 patients. Two patients were studied twice during the course of their illness. Eighteen patients were treated on the intensive care unit and two patients were treated on the ward. One patient (patient 4) died during the study period.

The relationship between the events during the study period and the skeletal muscle Po_2 is presented in Fig 1.

If the skeletal muscle Po_2 was more than 31.5 mm Hg, no shock occurred 4 hours before and 6 hours after the measurement. If skeletal muscle Po_2 was less than 3 mm Hg, shock always occurred during the period from 4 hours before to 6 hours after the measurement.

We compared the incidence of shock scores 1, 2, or 3 in patients with and patients without one or more skeletal muscle Po_2 values below 15 mm Hg during the study period. Significantly more patients had one or more periods of shock when at least one of the values was less than 15 mm Hg ($P = .007$) (Table 1). We also compared the incidence of shock scores 1, 2, or 3 in patients with and patients without one or more skeletal muscle Po_2 values of more than 30 mm Hg. Significantly fewer patients had one

or more periods of shock if their skeletal muscle Po_2 was at least once above 30 mm Hg ($P=.015$) (Table 1).

We calculated the risk of shock scores 1, 2, or 3 after a skeletal muscle Po_2 value below 22.5 mm Hg vs above 22.5 mm Hg. The same analysis was repeated in patients not requiring inotropic agents and in patients requiring inotropes. These calculations were made from 4 hours before to 6 hours after skeletal muscle Po_2 assessment and for the 2-hour period after the skeletal muscle Po_2 assessment. The latter period refers to the predictive value of skeletal muscle Po_2 assessment (Table 2).

If skeletal muscle Po_2 was below 22.5 mm Hg positive shock scores were found significantly more often than if the skeletal muscle Po_2 was above 22.5 mm Hg ($P<.01$). The predictive value of the median skeletal muscle Po_2 assessment in patients not using inotropic agents was even better ($P<.001$). In patients using inotropes, the skeletal muscle Po_2 assessment was not predictive with the 22.5 mm Hg limit ($P>.2$). The relationship between mean shock score and mean skeletal muscle Po_2 is presented in Fig 2. The relationship between skeletal muscle Po_2 and combined inotropic and shock score is shown in Fig 3. Incipient shock could not have been predicted by a decrease in blood pressure; metabolic acidosis; cool, clammy skin; or decreased urine output in these patients.

COMMENT

In this study, no shock occurred during the study period if skeletal muscle Po_2 was above 31.5 mm Hg. Skeletal

Fig 2.—Relationship between median skeletal muscle Po_2 and mean shock score and inotropes. Solid circles indicate no inotropes; solid triangles, dopamine hydrochloride and/or dobutamine hydrochloride, less than 20 mg/h; open triangles, dopamine hydrochloride and/or dobutamine hydrochloride, more than 20 mg/h; and open circles, epinephrine.

muscle Po_2 assessments predicted the risk of shock, because if the skeletal muscle Po_2 was below 22.5 mm Hg the risk of a positive shock score was higher than if skeletal muscle Po_2 was above 22.5 mm Hg. If the patient received no inotropes, skeletal muscle Po_2 assessment had a definite predictive value, because in these patients the risk of a positive shock score was 3.9 times higher if skeletal muscle Po_2 was below 22.5 mm Hg than if skeletal muscle Po_2 was above 22.5 mm Hg. If, in these patients not receiving inotropes, skeletal muscle Po_2 was below 22.5 mm Hg, a positive shock score occurred in 73% of the assessments during the subsequent period of 2 hours and a positive shock score always occurred in the period of 4 hours before and 6 hours after the skeletal muscle Po_2 assessment. These results demonstrate that, in critically ill patients, skeletal muscle oxygenation is decreased before clinical shock occurs (Fig 1).

The early decrease of tissue perfusion in critically ill

Fig 3.—Cumulative frequency curve of the skeletal muscle Po_2 and corresponding combined inotropic and shock score. 1 indicates score of 0 (n=25; median, 34 mm Hg); 2, score of 0.5 to 1.5 (n=37; median, 23.2 mm Hg); 3, score of 2.0 to 3.0 (n=44; median, 17.2 mm Hg); and 4, score of 3.5 or more (n=20; median, 11.2).

patients has been demonstrated by techniques more extensive and invasive than skeletal muscle Po_2 assessment. Skeletal muscle Po_2 was monitored with a multiwire surface electrode in 55 patients, and low values were found to correlate with a low circulatory blood volume.[10] This measurement enabled control of inspiratory oxygen supply and pharmacodynamic changes of local Po_2.[10] In another study, oxygen partial pressure was measured by an implanted Silastic catheter in the subcutaneous tissue of the arm in 33 postoperative patients on the day of the operation and the first 5 postoperative days. Tissue hypoxia was a common finding and was most pronounced immediately after abdominal, vascular, and cardiac operations. A supplemental bolus of infusion fluid increased low tissue Po_2 in all of 19 measurements, implicating hypovolemia as a common cause of postoperative tissue hypoxia.[11] Tissue Po_2 measurements were also performed by continuous in vivo measurements with a mass spectrometer in the deltoid muscle of nine patients in shock after severe trauma.[12] Tissue Po_2 values were lower postoperatively (20.2 mm Hg) despite the maintenance of Pao_2 above 13 mm Hg. In shock, low tissue Po_2 levels were found (15 mm Hg).[12]

In this study, skeletal muscle Po_2 assessment did not accurately predict clinical shock if the patient received inotropes, while in these patients the incidence of positive shock scores was 29% to 38% if the skeletal muscle Po_2 was below 22.5 mm Hg. The incidence of positive shock scores increased to 73% in patients not receiving inotropes. These findings support that inotropes such as dopamine, dobutamine, and epinephrine may maintain arterial blood pressure by increasing systemic vascular resistance at the cost of peripheral tissue perfusion. The administration of dopamine and dobutamine results in increases in cardiac index, pulmonary shunting, stroke volume, and mean arterial blood pressure.[13-18] Dobutamine preferentially strengthens the heart, while dopamine increases urinary output as well.[19] In only one patient (patient 21) skeletal muscle Po_2 was normal, although high doses of inotropes were necessary to maintain arterial blood pressure. If the inotropic drugs increase arterial blood pressure by augmenting cardiac output, while not increasing systemic vascular resistance, they could improve the skeletal muscle Po_2. However, the use of inotropes impaired skeletal muscle oxygenation, as the mean of the skeletal muscle Po_2 was below 22.5 mm Hg in 9 of 10 patients receiving inotropes (inotrope score, 3 or 4) (Fig 1). In these patients treated with inotropes, shock defined as inadequate tissue oxygenation occurred, but clinical shock as defined by the shock score did not occur in four patients.

Because systolic arterial blood pressure was artificially elevated in patients receiving inotropes, shock could not be diagnosed by the clinical criteria, such as decreased arterial blood pressure and/or impaired hourly urinary output. However, in the patients receiving inotropes, shock, defined as impaired tissue oxygenation, occurred in 9 of 10 patients. The treatment instituted with those medications increased arterial blood pressure, but they did not improve the oxygenation of skeletal muscle tissue.

Several conditions can be misleading. A decreased tissue Po_2 does not give additional information on the cause of shock. Decreased Po_2 could occur by a decrease of arterial Po_2, local circulatory disturbances, local inflammation, or increased oxygen consumption. Tissue Po_2 is not a metabolic marker.

Skeletal muscle Po_2 was decreased progressively if clinical signs of shock and/or treatment of shock by the administration of inotropes increased, as indicated by an increase of the combined inotrope and shock score (Fig 2). Thus, skeletal muscle Po_2 assessment enables the detection of the severity of shock. Further studies are necessary to assess whether keeping skeletal muscle Po_2 above 30 mm Hg during all periods of the illness may result in a lower morbidity and mortality of the patients at risk.

In conclusion, in critically ill patients, skeletal muscle Po_2 assessment estimates the severity of shock and is able to predict the risk of shock, provided no inotropes are given.

Oxidative Activity of Polymorphonuclear Leukocytes After Thermal Injury

Marek K. Dobke, MD, PhD; Edwin A. Deitch, MD;
Timothy J. Harnar, MD; Charles R. Baxter, MD

• Since defects in polymorphonuclear neutrophil (PMN) function are associated with an increased risk of infection, we measured the metabolic response of neutrophils from 23 burn patients with a mean burn size of 52%. Neutrophils from burn patients had a different pattern of oxygen consumption than control cells; the rate of Qo_2 at rest was higher, while the magnitude of the respiratory burst was lower in patient than in control PMNs, depending on whether the cells were incubated in media or normal serum. The burn-induced changes in patient PMN metabolism seem to be due to circulating factors, at least in part, since the pattern of increased resting and decreased stimulated Qo_2 could be transferred to control cells by incubating them in burn serum. Thus, a thermal injury alters neutrophil metabolism as well as systemic metabolism.
(*Arch Surg* 1989;124:856-859)

The development of impaired neutrophil function after a thermal injury is associated with an increased risk of the development of infectious complications.[1-3] Deitch et al,[4] as well as others,[1] have found a strong association between impaired in vitro neutrophil bactericidal activity and in vivo infection. Additionally, we have recently documented that the respiratory burst of control neutrophils incubated in blister fluid is depressed,[5] and that the inhibitory effect of burn blister fluid correlates with the extent of complement activation. Current studies, which are an extension of our previous work,[6-8] were performed to determine whether the metabolic response of peripheral neutrophils from burn victims was altered and, if so, whether these alterations were mediated by circulating humoral factors.

PATIENTS, MATERIALS, AND METHODS

Patients

Twenty-three burned patients (three women and 20 men), aged 19 to 57 years (average, 33 years), who sustained thermal injury of 20% to 86% of total body surface area (mean, 50%), with full-thickness injury ranging from 3% to 71% (mean, 25%) of the total body surface area, were studied. Ten of the patients died. Studies were begun within 24 hours after the injury in 12 cases, and within 72 hours in the remainder. When possible, samples were collected every two or three days for four weeks or until the burn wound healed. All patients were treated in the Dallas Burn Center at Parkland Memorial Hospital according to principles described elsewhere.[9]

Blood Samples

Normal venous blood was collected in specimen tubes (Vacutainers) from healthy donors after informed consent was obtained, according to requirements of the Code of Federal Regulation on Protection of Human Subjects. Neutrophils were separated from blood treated with heparin sodium by dextran sedimentation. After separation, washing, and hypotonic lysis of contaminating erythrocytes, the leukocytes (mean, 88% polymorphonuclear neutrophils [PMNs]) were suspended in HEPES-saline buffer. The viability of leukocytes as measured by trypan blue exclusion was greater than 90%.

Oxygen Consumption

Oxygen uptake of peripheral blood leukocytes (88% PMNs) was undertaken polarographically by the method of Nakamura et al.[10] Zymosan particles were preopsonized by incubation for 30 minutes at 37°C with pooled normal serum (60 mg/mL) for study of normal and burn PMN oxygen consumption (Figure). The lag period in the Qo_2 assay was defined as the time from the point when opsonized zymosan was added to the leukocyte suspension to the intersection of the extrapolated phagocytosis-connected decrease in oxygen concentration (respiratory burst) with the extrapolated resting state in oxygen concentration (Figure).[10]

Statistical Analysis

Results were expressed as the mean ± SEM. Unpaired Student's t test or χ^2 analysis was used to determine if the results were statistically different. Linear regression analysis was performed to determine if there was a relationship between the magnitude of injury and Qo_2. Statistical significance was achieved at $P<.05$ unless otherwise specified.

RESULTS

In the presence of a buffer, the patients' PMNs had increased "resting" levels of oxygen uptake, while Qo_2 of stimulated cells was similar to that of controls. Total O_2

Assay for oxygen consumption (Qo_2) of polymorphonuclear neutrophils by "resting" and stimulated cells. Rate of Qo_2 is determined from slope of linear portion of curve (between bars).

†Assays were performed using 85 burn serum specimens collected from 23 burn patients.

uptake capacity was even higher for burn leukocytes. Control cells, however, revealed a greater ability to respond to stimuli, as determined by the stimulation index (SI), which is defined as total O_2 uptake capacity divided by endogenous activity (Table 1). Control PMNs had higher levels of resting Qo_2, when these cells were assayed in burn serum than when they were assayed in autologous serum, indicating that burn serum increases Qo_2 to a greater extent than control serum. However, there were no differences in resting Qo_2 values between burn and control cells, when they were incubated in burn serum. The levels of resting Qo_2 were lowest for both burn and control PMNs, when they were incubated in HEPES-saline buffer (Tables 1 through 3).

On stimulation by preopsonized zymosan, patients' PMN Qo_2 was lower than that of control leukocytes (0.59 ± 0.02 vs 0.74 ± 0.02 nmol of O_2 per minute per 2.5×10^5 cells, $P<.05$), when the assay was performed in autologous serum (Tables 2 and 3). However, no difference in the levels of resting or stimulated Qo_2 was found between control and patient cells, when the assay was performed in burn serum (Tables 2 and 3). Additionally, in the presence of burn serum, the total O_2 uptake capacity and the SI were similar for control and patient PMNs. Because the SI is the ratio of total O_2 uptake capacity divided by endogenous activity, either an increase in the numerator or a decrease in the denominator would result in a high SI value. Indeed, since spontaneous O_2 uptake rates were low in the presence of HEPES-saline buffer, SI values were higher for this set of experiments than for cells incubated in sera. Burn cells had lowered SI values for autologous and control serum (Tables 1 through 3). Incubation in burn serum also resulted in decreased ability of control PMNs to develop an O_2 burst, as measured by the SI (Table 3).

Determination of the lag periods of the oxidative responses to zymosan stimulation revealed differences between PMN cells incubated in control vs burn serum. Burn cells responded faster in burn serum and HEPES-saline buffer than did control cells, but no difference was found in the times required to develop an O_2 burst between burn and control cells, when the assay was performed in normal serum. Furthermore, incubation of control cells in burn serum resulted in a shortening of their lag time, as compared with incubation in normal serum or HEPES-saline buffer, indicating that burn serum could alter O_2 metabolism of control PMNs (Table 4). Thus, exposure in vivo (burn PMN) or in vitro (control and burn PMN) to the "burn environment" resulted in decreased O_2 burst lag times.

To examine whether the changes in PMN oxidative metabolism were humorally mediated by burn serum factors in vivo, O_2 uptake rates were determined in patients who had undergone plasma exchange (where patient plasma is replaced with fresh-frozen plasma). To eliminate the possible influence of bacteremia, endotoxemia, or both, results of studies on patients in whom plasma exchange was performed only during the first 24 hours after burn are shown (Table 5). Plasma exchange reversed the increased resting and decreased stimulatory levels of Qo_2 as well as "normalized" the SI value. The total O_2 uptake capacity by the patients' PMNs was not changed by plasma exchange.

In this study involving moderately to severely burned patients, no correlation was found between the magnitude of resting or zymosan-stimulated PMN Qo_2 and the magnitude of the burn size in 15 patients who underwent PMN Qo_2 measurements within 48 hours of their burn injuries (data not shown). Sepsis did not alter resting or stimulated Qo_2, since the levels of Qo_2 were similar whether the assays were performed in buffered or control serum (Table 6).

Table 4.—Mean Values of Lag Period for Zymosan-Stimulated Burn and Normal Peripheral Blood Phagocytes (Mean, 88% Neutrophils) in Presence of Burn, Normal Serum, or HEPES-Saline Buffer*

Assay	No.†	Lag Period, s	P (Paired t test)

Likewise, the effect of burn serum on control PMN Qo_2 during septic episodes was similar to that of nonseptic serum (Table 6).

COMMENT

Previous studies have shown that the magnitude of the O_2 burst, as measured by stimulatory O_2 uptake, may be impaired in burn PMNs, and this may be a factor contributing to their reduced bactericidal activity.[3,7,9,10] However, a potential weakness of these and all standardized in vitro assays is the risk that the assay may not accurately reflect the complex interactions occurring in vivo. In fact, even blood drawing and processing of cells may change PMN activity.[9-11] Thus, in this study, in addition to measuring PMN Qo_2 after zymosan stimulation, we also measured the level of spontaneous (resting) PMN oxidative activity. Results of this study indicate that blood PMNs of burned patients may be activated in vivo and thus subsequently may be relatively refractory to in vitro stimulation.

An increased spontaneous activity of the burn PMNs in serum-free medium suggests that the cells were activated in vivo, since control cells processed similarly had lower endogenous rates of O_2 uptake. Furthermore, although burn PMNs incubated in autologous serum had lower levels of Qo_2 than control cells on stimulation with zymosan, total Qo_2 capacity (resting plus stimulated) was similar in control and burn cells. In fact, control cells assayed in burn serum acted like burn cells. The levels of resting O_2 uptake were increased and the stimulated and total Qo_2 capacity and the stimulation differential (stimulated minus resting O_2 uptake) were decreased. Thus, there were no significant differences in oxidative metabolism indexes between control and burn PMNs, when measured in burn serum.

Since the pattern of increased spontaneous and decreased stimulated Qo_2 also characterized control cells incubated in burn serum, it seems that these metabolic changes may be humorally mediated and are not necessarily limited to an in vivo burn cell-burn system interaction.[12] Limited observation on patient PMN responses, before and after plasma exchange, support the hypothesis that cells are activated in vivo by burn serum, since plasma exchange resulted in a decreased resting level and an increased stimulatory rate of Qo_2 and SI value, while total Qo_2 remained unchanged. However, it is unclear if, and to what

extent, postburn PMN dysfunction measured in vitro is reversible, since in vitro cell "washing" experiments failed to reverse the burn serum inhibitory effect of PMN cells, as determined by their bactericidal activity.[2]

Our previous work has demonstrated that the impaired ability of burn PMNs to increase Qo_2 during phagocytosis of opsonized zymosan correlated inversely with the degree of complement activation.[8] This relationship may be due to complement split products interacting with PMN receptors and resetting the resting level of oxidative metabolism (low-grade stimulation), although not triggering the respiratory burst. The concept of in vivo activation and subsequent deactivation or desensitization by complement activation products is not limited to oxidative responses, since some complement activation products (C3a, C3e, and C5a) have also been shown to regulate PMN migratory and secretory functions.[9,10,13]

Correlations between the level of complement activation and increasing spontaneous O_2 uptake levels and decreasing lag time values suggest that burn PMN oxidative activity changes are developed, at least in part, in a graded manner. This could also reflect changing proportions of activated-deactivated cells responding in an all-or-none manner.[7,8] The former concept is supported by recent studies documenting that the PMN oxidative response may be characterized as a graded reaction.[14] However, human PMNs exposed to activating factors may mobilize cryptic receptors, providing a new pool of available receptors that may replace receptors blocked following ligand binding. Whether such receptors are, or can become, fully functional in terms of PMN migratory, respiratory, and secretory responses has not been fully determined; however, the increase in C3b receptor number coincides with enhanced burn PMNs' bactericidal function.[15-21] Nevertheless, a decreased number of functional C3b receptors available for binding to preopsonized zymosan in vitro due to in vivo occupancy of these receptors might contribute to the decrease in stimulatory Qo_2 rates and decreased SI documented in our patients.[18,21]

Similarly, the elevated resting O_2 uptake by burn PMNs could be explained by low-grade in vivo binding, stimulation, or both of the C3b receptor by complement activation products.[8,16,20-22] An increase of cellular oxidative activity after exposure to burn serum is also suggested by the fact that the time necessary for activation of the respiratory burst enzymes (lag time) was shortened for burn and normal cells, when they were incubated in burn serum.

Our conclusions regarding changes in the burn PMN respiratory potential on stimulation must be restricted to C3b/C3b receptor mediated stimuli, such as preopsorized zymosan. This reservation is especially important, since we have shown that burn blister fluid will inhibit zymosan-stimulated, but not f-met-leu-phe–stimulated neutrophil Qo_2, indicating that blister fluid's inhibitory effect on the respiratory burst was mediated through the complement receptor.[5]

We believe that these observations have potential clinical implications. Principles of therapeutic intervention would be different if PMNs (or, in a wider sense, the entire immune system) were activated in vivo and at some point become refractory to subsequent stimuli due to deactivation or metabolic exhaustion rather than postburn dysfunction occurring as a result of true down regulation, suppression, or both.[22-24] For example, therapeutic intervention, using immunostimulants that affect uncommitted or suppressed cells, would not be expected to be effective if the immunologic defect is due to cellular exhaustion or deactivation. Thus, it is critical to accurately characterize the mechanisms responsible for impaired cellular function after thermal injury, to develop a rational therapeutic approach to bolster host defenses.

This investigation was supported in part by Public Health Service research grant GM 30705 from the National Institute of Health, Bethesda, Md.

RIGHT
NOW
Your investment
in ZINACEF is
starting to pay off.

ZINACEF® IM/IV GLAXO

sterile cefuroxime sodium

A sound investment in prophylaxis

Your choice of ZINACEF for surgical prophylaxis is an investment that can yield outstanding returns in lower postop infection rates, shortened hospital stays, and an improved bottom line for your patients.

Significant success against staphylococci

In a recent study, ZINACEF was shown to be "significantly more effective...than cefazolin in preventing postoperative wound infections following open-heart surgery"[1]—especially against *Staphylococcus aureus* and *S epidermidis*.

Reduces postoperative complications—infectious and financial

A recent nationwide analysis revealed that each postoperative wound infection represents a nonreimbursable loss to a hospital of $2,467, on average.[2] By reducing the rate of infection, ZINACEF can help reduce these losses.

Glaxo Glaxo Inc., Research Triangle Park, NC 27709

ZIN 346

ZINACEF® IM/IV GLAXO

sterile cefuroxime sodium

Brief summary. Before prescribing, consult complete Prescribing Information.

INDICATIONS AND USAGE: ZINACEF® is indicated for the treatment of patients with infections caused by susceptible strains of the designated organisms in the following diseases:

1. **Lower Respiratory Tract Infections**, including pneumonia, caused by *S pneumoniae* (formerly *D pneumoniae*), *H influenzae* (including ampicillin-resistant strains), *Klebsiella* sp, *S aureus* (penicillinase- and non-penicillinase-producing), *S pyogenes*, and *E coli*.
2. **Urinary Tract Infections** caused by *E coli* and *Klebsiella* sp.
3. **Skin and Skin Structure Infections** caused by *S aureus* (penicillinase- and non-penicillinase-producing), *S pyogenes*, *E coli*, *Klebsiella* sp, and *Enterobacter* sp.
4. **Septicemia** caused by *S aureus* (penicillinase- and non-penicillinase-producing), *S pneumoniae*, *E coli*, *H influenzae* (including ampicillin-resistant strains), and *Klebsiella* sp.
5. **Meningitis** caused by *S pneumoniae*, *H influenzae* (including ampicillin-resistant strains), *N meningitidis*, and *S aureus* (penicillinase- and non-penicillinase-producing).
6. **Gonorrhea:** Uncomplicated and disseminated gonococcal infections due to *N gonorrhoeae* (penicillinase- and non-penicillinase-producing strains) in both males and females.
7. **Bone and Joint Infections** caused by *S aureus* (including penicillinase- and non-penicillinase-producing strains).

Clinical microbiological studies in skin and skin structure infections frequently reveal the growth of susceptible strains of both aerobic and anaerobic organisms. ZINACEF has been used successfully in these mixed infections in which several organisms have been isolated. Appropriate cultures and susceptibility studies should be performed to determine the susceptibility of the causative organisms to ZINACEF.

Therapy may be started while awaiting the results of these studies; however, once these results become available, the antibiotic treatment should be adjusted accordingly. In certain cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, ZINACEF may be used concomitantly with an aminoglycoside (see **PRECAUTIONS**). The recommended doses of both antibiotics may be given depending on the severity of the infection and the patient's condition.

Prevention: The preoperative prophylactic administration of ZINACEF may prevent the growth of susceptible disease-causing bacteria and thereby may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures (eg, vaginal hysterectomy) that are classified as clean-contaminated or potentially contaminated procedures. Effective prophylactic use of antibiotics in surgery depends on the time of administration. ZINACEF® (sterile cefuroxime sodium, Glaxo) should usually be given one-half to one hour before the operation to allow sufficient time to achieve effective antibiotic concentrations in the wound tissues during the procedure. The dose should be repeated intraoperatively if the surgical procedure is lengthy.

Prophylactic administration is usually not required after the surgical procedure ends and should be stopped within 24 hours. In the majority of surgical procedures, continuing prophylactic administration of any antibiotic does not reduce the incidence of subsequent infections but will increase the possibility of adverse reactions and the development of bacterial resistance.

The perioperative use of ZINACEF has also been effective during open heart surgery for surgical patients in whom infections at the operative site would present a serious risk. For these patients it is recommended that ZINACEF therapy be continued for at least 48 hours after the surgical procedure ends. If an infection is present, specimens for culture should be obtained for the identification of the causative organism and appropriate antimicrobial therapy should be instituted.

CONTRAINDICATIONS: ZINACEF® is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS: BEFORE THERAPY WITH ZINACEF® IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE WHETHER THE PATIENT HAS HAD PREVIOUS HYPERSENSITIVITY REACTIONS TO CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. THIS PRODUCT SHOULD BE GIVEN CAUTIOUSLY TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. IF AN ALLERGIC REACTION TO ZINACEF OCCURS, DISCONTINUE THE DRUG. SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics alters normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *C difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated.

When the colitis is not relieved by drug discontinuance or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes of colitis should also be considered.

PRECAUTIONS: Although ZINACEF® rarely produces alterations in kidney function, evaluation of renal status during therapy is recommended, especially in seriously ill patients receiving the maximum doses. Cephalosporins should be given with caution to patients receiving concurrent treatment with potent diuretics as these regimens are suspected of adversely affecting renal function.

The total daily dose of ZINACEF should be reduced in patients with transient or persistent renal insufficiency because high and prolonged serum antibiotic concentrations can occur in such individuals from usual doses.

As with other antibiotics, prolonged use of ZINACEF may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection occurs during therapy, appropriate measures should be taken.

Broad-spectrum antibiotics should be prescribed with caution in individuals with a history of gastrointestinal disease, particularly colitis.

Nephrotoxicity has been reported following concomitant administration of aminoglycoside antibiotics and cephalosporins.

Interference with Laboratory Tests: A false-positive reaction for glucose in the urine may occur with copper reduction tests (Benedict's or Fehling's solution or with Clinitest® tablets), but not with enzyme-based tests for glycosuria (eg, Tes-Tape®). As a false-negative result may occur in the ferricyanide test, it is recommended that either the glucose oxidase or hexokinase method be used to determine blood plasma glucose levels in patients receiving ZINACEF.

Cefuroxime does not interfere with the assay of serum and urine creatinine by the alkaline picrate method.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Although no long-term studies in animals have been performed to evaluate carcinogenic potential, no mutagenic potential of cefuroxime was found in standard laboratory tests.

Reproductive studies revealed no impairment of fertility in animals.

Pregnancy: ***Teratogenic Effects: Pregnancy Category B:*** Reproduction studies have been performed in mice and rabbits at doses up to 60 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefuroxime. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: Since ZINACEF is excreted in human milk, caution should be exercised when ZINACEF is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children below 3 months of age have not been established. Accumulation of other members of the cephalosporin class in newborn infants (with resulting prolongation of drug half-life) has been reported.

ADVERSE REACTIONS: ZINACEF® is generally well tolerated. The most common adverse effects have been local reactions following intravenous administration. Other adverse reactions have been encountered only rarely.

Local Reactions: Thrombophlebitis has occurred with intravenous administration in 1 in 60 patients.

Gastrointestinal: Gastrointestinal symptoms occurred in 1 in 150 patients and included diarrhea (1 in 220 patients) and nausea (1 in 440 patients). Symptoms of pseudomembranous colitis can appear during or after antibiotic treatment.

Hypersensitivity Reactions: Hypersensitivity reactions have been reported in less than 1% of the patients treated with ZINACEF and include rash (1 in 125), Pruritus, urticaria, and positive Coombs' test each occurred in less than 1 in 250 patients, and, as with other cephalosporins, rare cases of anaphylaxis, erythema multiforme, and Stevens-Johnson syndrome have occurred.

Blood: A decrease in hemoglobin and hematocrit has been observed in 1 in 10 patients and transient eosinophilia in 1 in 14 patients. Less common reactions seen were transient neutropenia (less than 1 in 100 patients) and leukopenia (1 in 750 patients). A similar pattern and incidence was seen with other cephalosporins used in controlled studies.

Hepatic: Transient rise in SGOT and SGPT (1 in 25 patients), alkaline phosphatase (1 in 50 patients), LDH (1 in 75 patients), and bilirubin (1 in 500 patients) levels has been noted.

Kidney: Elevations in serum creatinine and/or blood ureanitrogen and a decreased creatinine clearance have been observed, but their relationship to cefuroxime is unknown.

HOW SUPPLIED ZINACEF® is a dry, white to off-white powder supplied in vials and infusion packs.

Each vial contains cefuroxime sodium equivalent to 750 mg, 1.5 g, or 7.5 g of cefuroxime. ZINACEF in the dry state should be stored between 15° to 30°C (59° to 86°F), and protected from light.

ASSISTANT DIRECTOR of MEDICAL EDUCATION in SURGERY

DIRECTOR, SURGICAL CRITICAL CARE and NUTRITION

MEMORIAL MEDICAL CENTER in Savannah, Georgia, is seeking a Board eligible/Board certified surgeon to join the Department of Surgery. MEMORIAL is a 475-bed tertiary center in southeast Georgia and serves a population of over 1,000,000.

Candidates should have a strong interest in teaching and research in addition to skills in trauma surgery, general surgery, and critical care/nutrition. Completion of a fellowship or similar experience is preferred.

This position offers a unique academic environment, university-trained colleagues, and a sound teaching program, which is accompanied by a highly attractive financial package.

Posttraumatic Autotransplantation of Spleen Tissue

Solly Mizrahi, MD; Amitai Bickel, MD;
Mahmud Haj, MD; Ida Lunski, MD; Benjamin Shtamler, MD

• Clinical and laboratory studies have documented high susceptibility to pneumococcal infection in asplenic humans and animals. Splenic autotransplantation has been suggested as a method of preserving function. Autotransplantation of irreparably damaged spleens in humans preserved splenic functions. Ten patients operated on for blunt abdominal trauma required unavoidable splenectomy. In each, autotransplantation of the removed spleen (roughly 50 g) was performed. Postoperative studies of splenic functions revealed disappearance of Howell-Jolly bodies from peripheral blood. Levels of IgM, which were initially significantly depressed, returned to normal and there were normal technetium Tc 99m sulfur colloid scans ten weeks after surgery. All patients are alive and healthy. Our data suggest that autotransplantation of spleen is a safe alternative method for preserving splenic function when total splenectomy is mandatory for hemostasis.
(*Arch Surg* 1989;124:863-865)

Splenectomy in children and adults may expose them to the danger of overwhelming infection and sepsis.[1-4] The major risk remains within the first two years after surgery.[5] Increased incidence of sepsis following splenectomy is attributed to the compromised humoral and cellular immune defense. The chief deficiencies are as follows: failure of antibody response to particulate antigen, depressed IgM levels, decreased properdin, decreased circulating T lymphocytes, and tuftsin deficiency.[6] As a result, every splenic injury is managed, when possible, by salvage procedures or nonsurgical observation.[7,8]

The surgical techniques for splenic salvage comprise application of topical hemostatic agents or omentum, with or without simple capsular suture; direct suture of the capsule and parenchyma; ligation of individual or segmental vessels; and partial splenectomy or application of absorbable net.[9] When the above methods fail to achieve hemostasis and splenectomy appears inevitable, the approach used is the autotransplantation of spleen tissue into the peritoneal cavity. The latter procedure has gained attention as an alternative method of splenic preservation. Its clinical use has been reported.[10-16]

In January 1984, the Surgical Service of Nahariya (Israel) General Hospital first started to use autotransplantation of splenic tissue in children and adults requiring splenectomy following blunt abdominal trauma. We present our three-year experience (January 1984 through December 1986) with this conservative surgical method.

PATIENTS AND METHODS

During the three years from January 1984 through December 1986, all patients hospitalized with blunt abdominal trauma were treated as follows: Those with obvious signs of intra-abdominal hemorrhage or peritonitis underwent abdominal surgical exploration after a suitable preparation. In patients whose abdominal surgical examination was equivocal, a peritoneal tap or lavage was performed. Abdominal computed tomography, scanning, or arteriography were not utilized as diagnostic tools in our series. Sixteen patients with shattered spleens, requiring splenectomy for hemostasis because all salvage attempts failed, underwent reimplantation of their splenic tissue. Ten of the 16 patients, those with a follow-up of 12 to 36 months, are described.

The technique used in all patients to implant the spleen tissue into omental pouches is a modification of the method described by Patel et al,[15] Williams et al,[17] and Kusminsky et al.[18] It consists of slicing by hand on a metal tray the waist or the poles of the removed spleen into 3-mm-thick slices weighing a total of 50 g and spreading the omentum on the abdominal wall, separating its two layers and placing the harvested splenic slices in between. The omental opening is sewn and marked with metal clips. This procedure is carried out after all other intra-abdominal injuries have been treated. The omentum, along with the autotransplanted spleen, is returned to its anatomical location.

All patients were followed up with blood smears for erythrocyte morphological studies, Howell-Jolly bodies were vigorously searched for by "blinded" evaluators, and quantitative serum IgM levels were determined on the operating day and 4, 8, and 12 weeks thereafter. Splenic scans were performed ten weeks after the implantation. All patients received 0.5 mL of pneumococcal polysaccharide vaccine subcutaneously following surgery.

The unpaired Student t test was used to compare differences between group means. Results are expressed as the mean ± SEM. Statistical significance was set as $P<.05$. According to the one-way analysis of variance, the means of the variables are significantly different.

RESULTS

Our series includes four females and six males, ranging in age from 8 to 34 years. All injuries sustained were the result of blunt abdominal trauma. Penetrating trauma producing severe splenic injury did not occur. The mechanisms of the injuries were falls, automobile-pedestrian accidents, or motor vehicle accidents. The patients' mean hospitalization time was 10.2 ± 2.27 days. Two patients were readmitted to the hospital for partial obstruction of

the small bowel and were conservatively treated (Table 1).

Immunoglobulin M levels were significantly reduced four weeks after surgery ($P<.01$). They rose to normal range four weeks later (Table 2). Radioisotope scans made with technetium Tc 99m sulfur colloid revealed functioning, implanted splenic tissue in all patients ten weeks after surgery (Figure). Peripheral blood smear examinations four weeks postoperatively confirmed the disappearance of Howell-Jolly bodies.

For a period of 12 to 36 months after the surgical procedure, no severe infection occurred in any of the patients.

COMMENT

In 1911, Kocher[19] stated, "Injury of the spleen demands excision of the gland. No evil effects follow its removal, while the danger of hemorrhage is effectually stopped." Seven decades later, advanced immunology has revealed the importance of the spleen in host defense, while improvements in supportive care have made conservative treatment safer.

The injured spleen is capable of satisfactory healing either spontaneously or following surgical intervention and repair. Autotransplantation as an alternative method for

spleen salvage has been carried out in men,[15,16,20] but its efficiency remains controversial.

According to Greco and Alvarez,[21] 80% of the spleen can be removed and the remnant will hypertrophy and protect the host against subsequent bacteremia. Their results support the contention that hilar vessels are not essential for function if identifiable blood vessels remain in continuity with the splenic remnant. Respectively, the microvasculature that regenerates into the reimplanted splenic tissue after initial necrosis is indistinguishable from that of the original organ.[22] This revascularized hypertrophied splenic tissue phagocytizes pneumococci from the bloodstream and appears to contribute to higher levels of pneumococcal antibody following immunization.[14,23]

The optimal site of splenic reimplantation remains unsettled. Experimental studies demonstrated that its seeding into omental pouches, as in our study, have a greater protective effect against pneumococcal septic challenges than do splenic tissue implants outside the portal circulation.[24,25]

The unanswered question is: what quantity of the reimplanted splenic tissue is necessary for complete protection against overwhelming postsplenectomy infection? Van Wyck et al[26] found that the splenic mass correlates directly with production of antibody to particulate intravenous antigen. Possession of greater than one third of the normal splenic mass showed a clear-cut protective edge over asplenia after intravenous challenge with live pneumococci. To confer protection, the critical splenic mass has to receive a critical volume of blood flow. In cases where part of the spleen left was in situ while reimplantation of the remnant occurred, only 1.5% of total splenic blood flow participated in the transplanted particles.[24]

Splenic autotransplantation alone, after maximal regeneration, partially protects against sepsis.[27,28] Orda et al[29] reported recurrent splenic tissue activity in patients who underwent splenectomy alone for trauma. All our patients showed normal functional capacity of the splenic implants ten weeks after surgery. Despite this capacity, the reimplantation remains an unproved modality. Moor et al[20] recently reported death from overwhelming postsplenectomy infection 15 months following splenic reimplantation.

Previous experimental studies have demonstrated the superiority of partial splenectomy over autotransplantation regarding its immune function. When total splenectomy is unavoidable, we found that reimplantation of the splenic tissue into omental pouches, followed by postoperative prophylactic antipneumococcal vaccine and antibiotics, provide a logical and simple alternative for preservation of some splenic function. The assumption that it will be functionally efficient and sufficient will require further confirmations.

Invited Editorial Comment

The recognition of delayed, overwhelming postsplenectomy sepsis and, more recently, the immediate postoperative immunologic consequences of splenectomy have provided a clear rationale for splenic salvage following injury. When splenorrhaphy is untenable due to extensive hilar disruption or inappropriate because of other life-threatening injuries, reimplantation of the excised spleen would seem a logical procedure. Indeed, this concept is supported by an extensive body of work using animals. Moreover, the feasibility of splenic autotransplantation has been demonstrated clinically, and at virtually no risk to the patient. But the skeptics continue to ask for objective evidence of immunologic/host-defense benefit. This report by Mizrahi and associates corroborates the clinical data from several other groups that document normalization of serum IgM and C3 levels as well as platelet counts, disappearance of Howell-Jolly bodies and target cells, more efficiently labeled erythrocyte clearance, and growth of splenic implants as evidenced by technetium Tc 99m sulfur colloid scanning. No doubt in progress are clinical studies to document restoration of tuftsin levels, enhanced production of antipolysaccharide IgG to immunization, as well as a variety of cell culture studies to define the critical role of the spleen in modulating immune cell traffic.

While splenic autotransplantation is no substitute for the intact spleen, emerging data, as reported above, are beginning to move this technique closer to clinical reality.

Recurrent Stenosis by Duplex Scan Following Carotid Endarterectomy

Vincent J. Bertin, MD; Fred R. Plecha, MD; Gregory J. Rogers, MD; Karen MacPherson, RNC; Judith Lund, LPN

• Between June 1984 and January 1986, 155 carotid endarterectomies were performed with routine shunting. Serial duplex scanning was performed during an 18-month period on 124 vessels. The results of this duplex scan review revealed the following data: A normal scan was obtained in 87/124 (70.1%). Recurrent stenosis was identified in 35/124 (28.1%), and an occluded vessel was identified in 2/124 (1.6%). Of the total recurrent stenosis group, recurrent stenosis was graded mild in 22/124 (17.7%), moderate in 7/124 (5.6%), and severe in 6/124 (4.8%). Of the 35 vessels with recurrent stenosis by duplex scanning, 22/35 (62.8%) were in female patients, and 13/35 (37.2%) were in male patients. Of the vessels with severe recurrent stenosis, 5/6 (83%) were in female patients. Recurrent stenosis following carotid endarterectomy is more common than appreciated clinically, and female patients in particular may be more prone to recurrent stenosis.

(*Arch Surg* 1989;124:866-869)

Carotid endarterectomy (CEA) is the most frequent procedure performed by vascular surgeons. During the past decade of noninvasive technologic advancements, numerous reports have indicated that recurrent stenosis following CEA is more frequent than previously realized. Reports of symptomatic (clinical) recurrence have been extremely low (in the range of 1% to 4%) in most series.[1,2]

With the advent of indirect noninvasive testing methods, the evidence of recurrence escalated. Most reports indicated that the range of recurrent stenosis following CEA was (is) between 10% and 13%.[3-6] Using direct (but nonduplex) modalities following CEA, particularly B-mode ultrasound, O'Donnell et al[7] found a 12.3% incidence of significant recurrent stenosis.

As technology progressed to duplex scanning, the recurrent stenosis rate following CEA continued to rise. A collective review of those CEA sites followed by duplex scanning reveals recurrent stenosis rates between 15% and 49%.[8-12] The reason for the wide variation in the "true" incidence of recurrent stenosis is strongly contingent on the entry point of the endarterectomy site into the series being reported.

The major purpose of this report is to present our experience with a consecutive series of patients who had undergone CEA and who were examined by serial duplex scanning during a recent 18-month period. The study focuses primarily on evaluation of serial duplex scans following CEA. The admission of patients into this study was systematically performed, and the subsequent analysis of the results should prove to be useful to the vascular surgeon who frequently performs this procedure.

PATIENTS, MATERIALS, AND METHODS

Operations

The study group consisted of 155 consecutive CEAs performed by two of us on 113 patients. Of the 155 potential endarterectomy sites available for serial duplex scanning and analysis, only 124 sites had complete data profiles, including at least two serially obtained scans. Thus, 31 CEA sites in 25 patients were not available for analysis due to incomplete duplex scan data or unavailability of follow-up. The data foundation for this report represents 124 CEA sites in 88 patients. There were 42 male and 46 female patients. The age range was from 40 to 87 years, with a mean age of 66 years. The number of "male" endarterectomy sites was 64, and the number of "female" endarterectomy sites was 60. The usual cardiovascular risk factors for all patients were represented. Hypertension was present in 67/88 (77%), diabetes in 37/88 (26%), smoking in 56/88 (59%), and previous myocardial infarction in 88 (33.4%).

The indications for the operation in the entire series were as follows: lateralizing hemispheric transient ischemic attack or amaurosis fugax in 90/155 (58%) and/or posthemispheric cerebrovascular accident with good recovery in 26/155 (17%). Endarterectomies were for nonhemispheric symptoms in 19/155 (12%), and prophylactic endarterectomies were performed in 20/155 (13%).

All patients were started preoperatively on a regimen of aspirin and dipyridamole (Persantine). All CEAs were performed with the patients under general anesthesia, and routine shunting was employed. All operations were performed by two of us (V.J.B. and F.R.P.).

Postoperative Follow-up

Serial duplex scans were obtained in all patients (except as mentioned previously), and each endarterectomy site in this report had at least *two* duplex scans obtained in serial fashion. All duplex scans were performed with a duplex scanner (Hoffrel 518) utilizing

a 7.5-MHz real-time ultrasound-imaging transducer and a 3-MHz pulsed Doppler transducer in the scan probe. The sample volume obtained in our system was approximately 2 mm^3. The carotid arteries were imaged in both longitudinal and transverse modes. The pulsed Doppler signal was audibly analyzed. In addition, on-line qualitative spectral analysis of the velocity waveform profile of the pulsed Doppler signal was achieved by the angioscan (Unigon Industries, Inc). Videotape recordings were made of both the B-mode image and the qualitative spectral analysis. All postoperative scans were interpreted by one of us (V.J.B.). Quantitative spectral analysis was not utilized in our vascular laboratory.

The endarterectomy sites were classified into normal (0% to 20%) stenosis, mild (20% to 40%) stenosis, moderate (40% to 60%) stenosis, severe (60% to 90%) stenosis, and occluded. This classification was based on the *qualitative* assessment of the amount of spectral broadening, together with the peak systolic and end diastolic frequencies. This criterion has a 90% absolute correlation with conventional angiography in our vascular laboratory in assessing preoperative carotid disease, and this same stratification was utilized in assessing endarterectomized vessels. The serially obtained postoperative scan reports were then graded and recorded on previously designed data sheets.

For ease of analysis, the scans were grouped into two groups. Group 1 was composed of scans that were obtained three to six months postoperatively, and group 2 was composed of scans that were obtained at 12 to 18 months.

In this analysis, in those scans with recurrent stenosis, criteria for *persistent recurrent stenosis* was the same duplex grade from scan group 1 to scan group 2; *progressive recurrent stenosis* was an increased grade from scan group 1 to scan group 2, and the criterion for *regression* was a diminution in grade from scan group 1 to scan group 2. The duplex scan data derived from the nonoperated-on contralateral carotid artery were not examined in this report. The data will be available in a future report.

RESULTS

Scan/CEA Site Data

Of the 155 CEAs performed, there were three perioperative strokes and one perioperative mortality that was not stroke related. The overall stroke morbidity was 3/155 (1.9%), and the combined early stroke morbidity and operative mortality was 4/155 (2.6%). During the follow-up period of 18 months, two patients sustained hemispheric infarcts—only one ipsilateral to the reconstructed carotid artery. Both of these patients had a good recovery from their stroke.

Of the 124 CEA sites available for analysis, ie, those in which at least two serial postoperative scans were obtained for analysis, the following results were obtained. These are summarized in Table 1. A normal scan was obtained in 87/124 (70%) of the carotid arteries. Total occlusion was discovered in two arteries, and both were clinically silent.

Recurrent carotid stenosis was identified in 35/124 (28.1%) of the endarterectomy sites analyzed. Further analysis of the recurrent stenosis group revealed mild recurrence in 22/124 (17.7%), moderate recurrence in 7/124 (5.6%), and severe recurrence in 6/124 (4.8%). Of the 35 arteries with recurrent stenosis, 22/35 (62%) were in women, and 13/35 (37.2%) were in men.

Analysis of the recurrent stenosis group by sex reveals that of 60 endarterectomy sites in female patients, recurrent stenosis was present in 22/60 (36.6%). Of the 64 endarterectomy sites in male patients, 13/64 (20%) showed recurrence. This difference was statistically significant to P less than .05.

Of the group with severe recurrent stenosis 5/6 (83%) were in endarterectomy sites in female patients. Of the endarterectomy sites with moderate recurrence, 5/7 (62%) were in female patients.

Spectrum of Recurrent Stenosis

The spectrum of recurrent stenosis was as follows: persistent recurrent stenosis was encountered in 11/35 (40%), and regression of stenosis was identified in 10/35 (28.6%). Of the group with severe recurrence, four vessels had severe recurrence documented on the first scan. None of these vessels demonstrated regression. Four vessels with mild recurrence on scan 1 progressed to moderate recurrence on scan 2. One vessel that revealed moderate recurrence on scan 1 progressed to severe recurrence on scan 2. Six vessels that were normal on scan 1 progressed to moderate recurrence on scan 2. Only one patient with moderate recurrence on scan 1 regressed to normal on scan 2. Nine patients with mild recurrence on scan 1 regressed to normal on scan 2. Overall, no consistent pattern of recurrence was seen. One vessel with mild recurrence on scan 1 progressed to severe recurrence on scan 2 and concomitantly developed ipsilateral amaurosis fugax. This patient underwent intra-arterial digital subtraction angiography (DSA) study that corroborated the recurrence and subsequently underwent a redo endarterectomy with a vein patch at 16 months after the initial procedure. The findings were consistent with intimal hyperplasia. This patient was female. One other female patient with severe recurrence (unilateral) by scan developed persistent nonhemispheric symptoms following bilateral CEA. Results of an intra-arterial DSA study corroborated the scan findings, and the patient also underwent a successful redo endarterectomy with a vein patch angioplasty. This procedure was performed 22 months after the primary procedure.

Of the patients with moderate recurrence, two developed nonhemispheric symptoms, and one developed lateralizing hemispheric symptoms to the contralateral carotid artery. This patient underwent conventional angiography that revealed a normal endarterectomy site and confirmed an ulcerative lesion in the symptomatic carotid artery. Overall in this study the symptomatic recurrence rate was 5/124 (4%). Contrast studies obtained during the study were confined to patients with recurrent ipsilateral symptoms. Additionally, patients who developed cerebral hemispheric

contralateral symptoms during the study period also underwent contrast studies. A total of *six* was obtained. Results of four of *five* intra-arterial DSA studies corroborated the findings by duplex scan, and one conventional angiogram suggested overreading by duplex scan. This was a patient who had moderate recurrence by scan.

COMMENT

Most reports of duplex scanning following CEA include patients entered at different times following the procedure. In this study, patients were consecutively entered during a recent 18-month period. Serial duplex scanning should provide data that are helpful in understanding the early healing response following endarterectomy. Adding to the uniformity of this study is that all procedures were performed with a similar technique, including routine shunting. The overall stroke morbidity and mortality reported are consistent with previous reports. Clinical recurrence is rare; however, noninvasive testing indicates that clinical recurrence underestimates the true recurrence.

A brief review of reports that have detected recurrent stenosis by indirect, as well as direct, noninvasive methods aids in placing our data in proper perspective. Serial indirect noninvasive testing (OPG-K) was reported by Baker et al.[3] The recurrent stenosis rate of serially tested vessels was approximately 13%. This finding was corroborated by numerous other investigators.[4-6]

Direct (nonduplex) noninvasive testing utilizing B-mode ultrasound (dopscan), or continuous-wave Doppler measurements, also indicated a higher rate of recurrent stenosis than clinical criteria would predict. The range of recurrence in these studies was between 8% and 15%.[7,13]

Early reports with duplex scanning indicated a quantum leap in recurrent stenosis, with Bodily et al[8] and Zierler et al[9] reporting recurrence rates of 49% and 36%, respectively. The former study utilized a complex quantitative analysis of the spectrum obtained from the endarterectomy site, providing skepticism to these results. More recent reports utilizing duplex scanning following CEA indicate recurrence rates ranging between 15% and 25%.[10-12,14] It is clear that with improved technology and improved sensitivity of the testing methods, the rate of recurrent stenosis is higher than anticipated. (The crucial question centers on the significance of these duplex recurrences.)

At first glance, the recurrent stenosis rate following endarterectomy of nearly 30% in this study is high; however, most of the recurrences were in the mild category. Moderate to severe recurrence or occluded vessels following endarterectomy in this report accounted for 15 vessels or 12.1% overall. Interestingly, this moderate to severe recurrent stenosis group or occluded group will include those patients with recurrence approaching hemodynamic significance. One would expect the recurrence rate of these vessels to be quite similar to recurrence rates detected by indirect methods.

For the most part, mild recurrence by duplex scanning probably represents arterial wall compliance changes that are probably of little significance. However, one of our patients with initially mild recurrence on scan 1 progressed to severe recurrence on scan 2. Other reports have indicated this occurrence of disease progression.[10] Even though the endarterectomy site in most patients is stable, there is some element of unpredictability.

Four vessels in our study with severe recurrence on scan 1 and the two occluded vessels constitute an interesting group. Since we did not perform continuous-wave Doppler measurements intraoperatively, nor perform completion angiography routinely, it is conceivable that these vessels could represent residual rather than recurrent stenosis. The topic of residual stenosis has been recently reviewed thoroughly by Barnes et al.[15] Since that report, we have begun to use continuous-wave Doppler measurements intraoperatively to assess the carotid arteries following endarterectomy to diminish the possibility of residual stenosis.

A major dilemma is the patient who develops severe recurrence by duplex scan and remains clinically asymptomatic. How should this patient be managed? Nicholls et al[10] reported a 17% incidence of severe recurrent stenosis that persisted. Severe stenosis in their study was defined as a 50% lesion by qualitative analysis of the pulsed Doppler spectrum. None of these patients developed ipsilateral hemispheric symptoms during a mean follow-up of 18 months. Their conclusion was that postendarterectomy recurrent stenosis may not have the same stroke potential as the primary atherosclerotic plaque.[10] Corroboratory evidence for this hypothesis is provided by O'Donnell et al.[7] In this study, 276 endarterectomy sites were followed with B-mode ultrasound. Twenty-six vessels demonstrated recurrent stenosis without occlusion. The surface features of the plaque were smooth in 22 of 26 vessels examined by high-resolution B-mode ultrasound. Moreover, there was only an 8% incidence of plaque hemorrhage in those lesions contrasted with a 62% incidence of plaque hemorrhage in preoperative atherosclerotic plaques. They further suggested that recurrent carotid lesions have different morphological characteristics and are less dangerous (clinically) than the primary lesion.[7] Based on these studies, our policy in this group of patients is to question the patients with severe recurrence by duplex scan in detail as to recurrent symptoms. If none exist, then we are content with a noninvasive follow-up.

In our study, it is clear that the endarterectomy site most often remains stable; however, there is a subset of patients who possibly undergo a dynamic healing process. This concept is supported by our high incidence of progression and regression of stenosis by scan. Schultz et al[16] and Blaisdell et al[17] documented progression and regression of carotid lesions after endarterectomy using conventional angiography in serial fashion. Serial intravenous DSA studies, as well as serial indirect noninvasive studies, have also suggested this progression and regression of stenosis following CEA.[3,18,19] It is likely that the early regression and progression of disease following CEA have always been present, except that current testing methods are more sensitive to these early changes. The information, to date, suggests strongly that the healing response may be dynamic and unpredictable in certain patients.

A certain subset of patients, probably female, may possibly exhibit an excessive healing response following CEA. In this study, the female recurrence was significantly greater than the male recurrence as detected by duplex scanning. However, the absolute numbers are small, and the validity may be suspect because of the small group. A collective comparison of male and female recurrent stenosis by duplex scan following CEA is presented in Table 2. It is clear from these results that recurrent stenosis in most duplex studies reported to this date is predominantly female. The female predilection in the duplex studies reported is statistically significant to P less than .001. This should not be too surprising on a pathophysiologic basis. Reports of increased platelet aggregation and adhesiveness in female patients have appeared often in the literature. An accelerated intimal hyperplasia response in female patients has also been postulated and could conceivably account for these early lesions.[10] The Canadian Cooperative

Study[20] suggests that female patients may indeed not respond to antiplatelet treatment before surgical intervention. Therefore, no postoperative benefit should be expected. It is possible, but not proved, that the proclivity for increased recurrent stenosis in female patients may be due to platelet factors. Experimental studies of platelet aggregations induced by adenosine diphosphate have indicated that platelets from female patients were more responsive than platelets from male patients to the aggregating stimulus. It is unclear whether the increased aggregation response in female patients may be hormonally related. Further research on the interactions of smooth-muscle cells, fibroblasts, and platelet factors in the different sexes should provide useful information.[21,22]

If not hematologic factors, then could the penchant for recurrence in female patients by duplex scanning be a technical phenomenon? Female patients may have a small-caliber internal carotid artery in relation to the residual lumen diameter and, therefore, a resultant larger sample volume. Most, if not all, duplex scanners, to date, do not automatically adjust sample volume based on vessel diameters. If the sample volume is too large (eg, in a small-caliber vessel), then the resultant spectrum of the pulsed Doppler signal may broaden and yield an artificial flow disturbance.[23,24] If recurrent stenosis were an artifact created by too large a sample volume, then one would not expect changes on serial examinations of the same vessel, particularly when the same points in the vessel are examined and the Doppler probe angle is maintained at a relatively constant angle.

Contrarily, if a large sample volume is responsible, then one would expect that a vein patch angioplasty with a resultant larger reconstructed artery would yield a lower incidence of recurrent stenosis. A recent study by Sanders et al[24] in which a vein patch angioplasty was performed in 81% of the primary CEAs is interesting to review. Their follow-up consisted of duplex scanning, as well as intravenous DSA studies. Their recurrent stenosis rate was in the low range of 4% to 12%, although in this study, they only considered severe recurrent stenosis to be significant and essentially neglected the group with moderate recurrence. It is still plausible that some element of recurrent stenosis by duplex scan is a sample volume phenomenon, but it may be a minor component. More studies that actually measure intraluminal diameters after CEA, as well as improving technology with on-line measurements of sample volume and residual lumen diameters, may determine the true incidence of recurrent stenosis.

In conclusion, the purpose of our study was to report our early results with serial duplex scanning performed on a consecutive series of patients who were undergoing CEA. We have found that recurrent stenosis by duplex scanning is more common than appreciated by clinical evaluation. Recurrent stenosis approaching or achieving hemodynamic significance is similar to that predicted by earlier indirect noninvasive methods. The healing response following CEA is unpredictable in certain patients. The recurrence rate as detected by duplex scanning techniques is significantly higher in female patients. We hope the information provided in this study will be useful to vascular surgeons who frequently perform this procedure.

Primary Aortoduodenal Fistula

Diagnosis by Computed Tomography

Ibrahim M. Ibrahim, MD; Joseph S. Raccuia, MD; Joseph Micale, MD; Asham Zafar, MD

• A primary fistula between the abdominal aorta and the duodenum is rare and usually fatal. Computed tomography in a symptomatic but stable patient enabled preoperative evaluation and even diagnosis of abnormal communications, real or incipient, between the vascular and enteric system. This case demonstrated the effectiveness, ease, and low cost of documenting a primary aortoduodenal fistula. Surgical results were ultimately improved by initiating early intervention and aggressive management. Therapeutic principles included early intervention with aneurysmectomy, duodenorrhaphy, and extra-anatomic bypass. Anatomic graft placement may be acceptable in selected cases.

(*Arch Surg* 1989;124:870-871)

Less than 200 cases of primary aortoduodenal fistulas have been reported since the original description by Sir Astley Cooper[1] in 1822, and the first report by Salmon[2] in 1843. Although secondary aortoduodenal fistulas have been increasingly recognized as a late complication of aortic reconstruction, a primary aortoenteric fistula continues to be a rare phenomenon.

Approximately 80% of the reported cases of a primary aortoduodenal fistula involve the aorta and duodenum.[3-8] Tuberculosis, syphilis, and other bacterial agents can lead to a primary aortoduodenal fistula, but the most common cause today is an atherosclerotic aneurysm that erodes into the duodenum. Surgical therapy, while mandatory, carries a very high mortality and morbidity primarily because of the difficulty and delay in establishing the diagnosis.[9] This case report emphasizes the importance of establishing a preoperative diagnosis by computed tomography (CT), thereby enabling prompt and aggressive surgery.

REPORT OF A CASE

A 60-year-old man was hospitalized for melena. He had been treated, with no relief, with nonsteroidal anti-inflammatory agents and other analgesics for three months for back pain, despite the absence of radiologic confirmation of significant osteoarthritis. He had no history of surgery. At admission, he was noted to have low-grade fever, mild abdominal tenderness and fullness to deep palpation, and melenic stools. All peripheral pulses were palpable and full. Gastric aspirate was negative for blood. The complete blood count revealed significant anemia and elevation of the white blood cell count. He was treated with broad-spectrum antibiotics. An intra-abdominal or retroperitoneal abscess was suspected. A CT scan of the abdomen was performed that revealed the presence of an abdominal aortic aneurysm with gas in the surrounding tissue (Figure). The diagnosis of a primary aortoduodenal fistula was made on this basis, and the patient was immediately transferred to the operating room. At exploration, an extensive phlegmon of the retroperitoneum was encountered, surrounding a large pulsatile mass. A periaortic hematoma and erosion of the aneurysm into the duodenum were confirmed. Vascular control was obtained by sequential clamping of the common iliac arteries and infrarenal aorta. All grossly infected and necrotic tissue were excised. The infrarenal aorta and iliac arteries were oversewn with nonabsorbable, monofilament suture material. The duodenum was closed in two layers. The omentum was transposed to the retroperitoneum to cover the aortic closure. Following closure of the abdomen and repreparing of the patient, an axillobifemoral bypass was performed. Because of the significant time lapse between aortic clamping and reestablishment of femoral blood flow (3½ hours), significant rhabdomyolysis and peripheral neuropathy developed. This was manifested by a marked elevation of the creatine kinase level, weakness, and paresis from the pelvis down. He was treated with alkylating agents to prevent renal failure. During the next few months, he regained almost complete function of his lower extremities and continued to have adequately palpable peripheral pulses. He has been doing well 18 months postoperatively.

COMMENT

To avoid the lethal consequences of an aortoenteric fistula, an expeditious preoperative diagnosis is essential. Unfortunately, a preoperative diagnosis is uncommon.[9-11] In the absence of a history of aortic surgery, the diagnosis of an aortoenteric fistula requires a high index of suspicion. Frequently, the signs and symptoms are nonspecific. Upper gastrointestinal tract bleeding associated with back pain is present in approximately 50% of the cases.

Upper gastrointestinal tract endoscopy is helpful when the pathologic condition of the fourth portion of the duodenum is visualized. Occasionally, an aortic graft can be seen through the duodenal fistula with a secondary

Computed tomographic scan demonstrates large, calcified abdominal aortic aneurysm and air in aortic wall (small arrowheads), periaortic space (large arrowheads), and duodenum (D).

ortoduodenal fistula.[3] Endoscopy is also helpful in ruling out other more common causes of upper gastrointestinal tract bleeding. Unfortunately, it can be misleading in that such pathologic entities can coexist with an aortoduodenal fistula.[6] Magnetic resonance imaging has also been used to evaluate abdominal aortic aneurysms and has been shown to be just as reliable as CT and ultrasonography in routine screening.[12,13] Atherosclerotic plaques and a thrombus are seen as areas of eccentric thickening of the aneurysm wall. An organized thrombus, as well as flow abnormalities, can be identified by changes in intensity with variations of echo times. Coronal and sagittal sections clearly depict the length of the aneurysm, as well as the relationship of the abdominal aortic aneurysm to the renal arteries.[14] The use of magnetic resonance imaging has been advocated in the assessment of unusual abdominal aortic aneurysms when ultrasound and CT scans are equivocal.[15]

Computed tomography is unique in that a positive diagnosis of an aortoenteric fistula is possible. Several authors have, in fact, documented the reliability and advantages over other diagnostic modalities, focusing as well on the ability to diagnose a ruptured aneurysm in the stable patient.[12-20]

A primary aortoduodenal fistula should be considered if extraluminal gas is present in the periaortic region in the absence of previous aortic surgery. Gas has also been noted within the calcified rim of the aneurysm in association with an adherent loop of intestine.[5,16] A primary aortoduodenal fistula has also been diagnosed by CT, with the finding of a duodenum with a retroperitoneal tear stretched over the aneurysm.[21] These observations are, in fact, difficult to establish with certainty since a stretched duodenum over an abdominal aortic aneurysm can simulate actual fistulization.

Although most patients survive the initial herald bleed, a third die within the first six to 12 hours due to massive hemorrhage.[3,5,7,10,22] It is clear that the gravity of this disorder makes accurate diagnosis crucial, a situation that now appears to be significantly aided by CT scanning.

Surgical management of a primary aortoduodenal fistula must be individualized. Resection of the diseased aorta, closure of the duodenum, and in situ bypass have been advocated and successfully implemented. However, an in situ bypass has been contraindicated if gross infection is apparent in the general field. There is general agreement that the presence of gross purulent material precludes in situ placement with synthetic graft material and that an extra-anatomic bypass is clearly indicated in such cases.[3,11,22,23]

The lethal nature of a primary aortoduodenal fistula is due to its subtle nature and concomitant delay in diagnosis. Computed tomography offers a quick, inexpensive, and accurate method of diagnosing a primary aortoduodenal fistula. It can assist in evaluating the structural integrity of the aneurysmal aortic wall, and it can distinguish the symptomatic patient who has a confirmed aortic rupture and fistula from the one who is symptomatic, stable, and without a rupture. Early confirmation of the former will prompt immediate surgery and thereby yield improved results in this otherwise catastrophic situation.

Hernia Uterus Inguinale Associated With Unicornuate Uterus

David C. Elliott, MD; Thomas E. Beam, MD; Thomas S. Denapoli, MD

• Hernia uterus inguinale, a condition in which endometrium and myometrium are found in an ectopic location in the inguinal canal, is a rare congenital abnormality in women. A woman with a normal number of chromosomes (46,XX) demonstrated the presence of a uterus, fallopian tube, and ovary in an inguinal hernia associated with a unicornuate uterus. This represents a unique abnormality in the spectrum of lateral fusion defects associated with müllerian ductal development, which normally proceeds as the right and left systems fuse and form the uterus, cervix, and four fifths of the vagina. In this patient, the left müllerian system apparently failed to fuse with the right, instead assuming a location within the patient's inguinal canal.

(*Arch Surg* 1989;124:872-873)

While an ovary is a relatively frequent finding in indirect hernias in girls and frequently is incarcerated, this is less frequently seen in adults. We describe an unusual finding of a rudimentary uterus, fallopian tube, and ovary incarcerated in a hernia sac in a woman who was recently pregnant.

REPORT OF A CASE

A 19-year-old woman presented to the emergency department complaining of pain in a left groin bulge. She had noted the mass in her left inguinal region two years previously. It had caused her mild discomfort occasionally during her menstrual periods, but the latest episode of pain, beginning 48 hours previously, was severe and unrelenting.

The patient's medical history was notable for commencement of menarche at age 10 years; she typically now had five days of menstrual flow every 28 days. Her last menstrual period had been ten weeks before her emergency department visit. She had been diagnosed by urinary human chorionic gonadotropin testing six weeks earlier as being pregnant and for personal reasons elected to terminate the pregnancy by suction curettage one week before admission to the hospital.

Physical examination revealed a phenotypically normal-appearing woman. Breast development was compatible with Tanner stage 5. A 3×2-cm round, exquisitely tender mass occupied the left inguinal area. Strong Doppler flow was present. There were no signs of infection. The pelvic examination was notable for a normal female escutcheon as well as fully developed labia, urethra, and vagina. The cervix appeared to be normal, and bimanual examination revealed what felt to be a normal anteverted uterus. No adnexal masses were appreciated.

Fig 1.—Microscopic section of resected groin mass demonstrating endometrial (E) and myometrial (M) tissue (magnification × 40).

The patient was taken to the operating room with the presumed diagnosis of an incarcerated ovary in an inguinal hernia. Surgical exploration of the left groin revealed what appeared to be an ovary, fallopian tube, and a 4×3-cm adherent mass. All contents were resected and sent for pathologic examination, revealing mature ovarian tissue, a fallopian tube, and endometrial and myometrial tissue consistent with a rudimentary uterus. Evidence of surrounding endometriosis was also noted. The corpus uteri histologically showed evidence of recent gestation, suggested by

Fig 2.—Hysterosalpingogram demonstrating unicornuate uterus, right salpinx, and ovary.

the predominance of tortuous, crowded glands with focal involutional changes within the endometrium, consistent with the Arias-Stella phenomenon (Fig 1.)[1]

After surgery, the patient's symptoms abated, and she fully recovered. Further studies were conducted to define her anatomy: a pelvic ultrasound showed a normal-appearing right ovary, uterus, and right kidney (no left kidney or ovary was identified); an excretory urogram was notable for a left pelvic kidney; a hysterosalpingogram revealed a normal right ovary and salpinx connected to a unicornuate uterus (Fig 2); and peripheral lymphocyte karyotype showed a normal 46,XX pattern.

COMMENT

When the medical literature is reviewed, only four cases of hernia uterus inguinale in women have been reported. In 1948, Thomson[2] reported the case of a phenotypically normal woman with vaginal agenesis and bilateral inguinal herniae, each containing a uterus, ovary, and fallopian tube. In 1923, Deutschman[3] reported a nearly identical case. In 1980, Riggall and Cantor[4] described a 16-year-old girl with vaginal agenesis and a left inguinal hernia containing uterine tissue, ovary, and fallopian tube; additionally, karyotyping had been performed, revealing a normal 46,XX pattern. In 1970, Mahmood[5] reported the case of a multiparous 37-year-old woman who incarcerated the nongravid left horn of her bicornuate uterus in a left inguinal hernia during the 37th week of her fifth pregnancy.

Our case report illustrates the presence of a rudimentary

Fig 3.—Spectrum of müllerian duct lateral fusion defects. A, Uterus septus; B, uterus bicornis unicollis; C, uterus bicornis bicollis; D, uterus unicornis; and E, müllerian agenesis (Mayer-Rokitansky-Kuster-Hauser syndrome).

uterine horn in an inguinal hernia associated with a unicornuate uterus, a unique abnormality in the spectrum of müllerian duct lateral fusion defects. This spectrum (Fig 3) ranges from complete absence of the vagina and uterus (Mayer-Rokitansky-Kuster-Hauser syndrome) to the uterus septus (septate uterus). In the middle of the spectrum lies the uterus bicornis bicollis (didelphic uterus), uterus bicornis unicollis (bicornuate uterus), uterus unicornis (unicornuate uterus), and the rare abnormalities described above by Riggall and Cantor, Thomson, and Deutschman. Embryologically, these variants occur when the two müllerian ducts fail to fuse properly in the midline, normally giving rise to the müllerian tubercle, which matures to form the uterus, cervix, and four fifths of the vagina. The case reported in this article illustrates a new variant among lateral fusion abnormalities, in which one can speculate that the right müllerian duct underwent expected maturation, forming a classic unicornuate uterus, capable of normal menstrual cycles and reproductive function, while a defect in the left-sided müllerian system during gestation resulted in failure of its fusion with the right-sided system, instead following the ovary in its aberrant migration into the inguinal canal.

A New Surgical Localization Technique for Biopsy in Patients With Nipple Discharge

Arindam Choudhury, MD; Paul A. Wengert, Jr, MD; J. Stanley Smith, Jr, MD

• In a series of 12 patients with bloody nipple discharge, a new technique of mammary ductal localization was used to identify the duct responsible for the discharge and assure its complete removal for pathological diagnosis. This procedure utilizes a 30-gauge anterior chamber needle that is gently advanced into the offending duct, and methylene blue dye is injected to outline the involved duct for easy dissection though a circumareolar incision. This provides the pathologist with an intact specimen and avoids the problems associated with specimen roentgenography or loss of a ductal probe during the procedure. Because we feel that all patients with a bloody nipple discharge warrant a biopsy, this procedure provides a safe, rapid, effective method and allows the biopsy to be done on an outpatient basis.

(*Arch Surg* 1989;124:874-875)

In this era of increased public awareness of breast cancer, many patients are performing breast self-examinations. One common finding is a discharge from one or both nipples. This fluid can be expressed by light manual palpation about the areola or it may spontaneously discharge with the patient noting blood or fluid on her clothing. While this symptom may resolve spontaneously, persistent nipple discharge, especially if bloody, needs further evaluation. Such nipple discharge frequently is limited to one or two individual ducts, and there is usually no associated palpable mass. Surgical excision is frequently required to make a definitive diagnosis and relieve the symptoms; in fact, blood in the nipple discharge is the primary indication for microchodectomy. In evaluating 12 patients with bloody nipple discharge in December 1985, we found the following technique of ductal localization for biopsy to be helpful in excising the entire suspected lesion.

TECHNIQUE

The technique uses a 30-gauge "anterior chamber" needle. An anterior chamber needle is a malleable blunt-tipped, nonbeveled needle that acts like a probe and can be passed easily into the small ducts of the nipple.

Under sterile conditions, discharge is expressed from the breast and duct in question. The 30-gauge anterior chamber needle is passed into the duct. Then methylene blue dye is diluted to half strength and is injected through the needle using a small syringe (insulin or 3-mL syringe) as shown in the Figure. Approximately 2 to 3 mL of dye is needed to get the desired effect. The injection should be done very gradually and undue pressure should not be exerted on the duct so that dye is not extravasated from the end of the nipple. Once the dye is placed, a circumareolar incision is used nearest the point of needle entry, and the ducts and lobule identified with the dye are carefully dissected away for biopsy. The duct is followed from the undersurface of the nipple all the way to the periphery containing the dye. This specimen containing

Insertion of anterior chamber needle into duct with injection of methylene blue dye through major duct and its major tributaries.

ct and part of the lobule of the breast is sent for ction. The specimen is fixed in toto and representa- then made longitudinally of the area of the duct.

tients we were able to identify the appropriate ductal sponsible for the discharge as documented by the al examination. All 12 patients revealed benign intra- pillomas and none has had nipple discharge postopera- er one year of follow-up.

COMMENT

pple discharge has been classified into three catego- clear, serous, and bloody.[1] All three types of discharge e a certain predilection to be cancerous. The occurrence cancer is associated with serous and bloody discharge to 50% of the time as reported in several series.[1-4] pple discharge associated with nonpalpable lesions, ad- ocarcinoma, fibrosarcoma, liposarcoma, and malignant elanoma have been reported.[2-4] Therefore, microchodec- my is indicated in all cases of bloody nipple discharge. lthough the malignant potential of each of these lesions ries, the natural progression of carcinoma warrants the rgeon to do a thorough dissection as a first step in eating lesions presenting with nipple discharge.

Intraductal papillomas are the most common cause of enign bloody discharge and are often so small they cannot e readily seen without a microscope. This has led to the evelopment of techniques to identify the mammary ducts nvolved so that the entire duct can be removed for xamination.

Funderburk and Syphax[3] in 1969 described the technique f contrast mammography, which helped to identify by oentgenography the lobule producing discharge. The tech- ique has some disadvantages, such as dye reaction and extravasation, that render the study invalid in a small percentage of patients. It also requires the coordination of the radiologist and the surgeon—which may be time-consuming at most breast centers, although quite feasible. Our proposal of injecting methylene blue dye into the discharge-producing lobules is a safe, effective, and time-efficient substitute to contrast mammography. It has the major advantage of outlining the affected segment during the time of actual surgery and results in little extravasation so long as undue pressure is not used for injection.

Another commonly used technique involves cannulation of the draining duct with a lacrimal duct probe and then removing the probe-containing duct. This is much simpler than contrast mammography but may be complicated by dislodgment of the probe and therefore loss of the duct during the time of surgery. We have found the injection of methylene blue dye to easily outline the ducts involved during the surgical procedure and also to outline the major branches of the main duct that may be involved with the process causing the nipple discharge. This has made the procedure simpler and allows for a complete excision of the duct, with the patient under a local anesthetic in an outpatient setting.

Safety in Transfusion Practice: Is It Safe to Eliminate the Major Crossmatch for Selected Patients?

Ira A. Shulman, MD, Donald Kent, MT

If a patient has no clinically significant unexpected antibodies, a major crossmatch is not required prior to blood transfusion so long as a test method that demonstrates ABO incompatibility is done. In this study, the safety of using a noncrossmatch method for detecting ABO incompatibility was compared with the use of an immediate spin crossmatch (ISCX). This noncrossmatch method consisted of the duplicate ABO testing of blood recipients, the repeated ABO testing of donor blood, and a clerical check to assure that only ABO matched or compatible blood was selected for transfusion. During the one-year study, 7124 patient samples were tested in duplicate for ABO, 26 942 U of red blood cells received from blood collection facilities were retested for ABO, and 23 962 U of blood selected for transfusion based on the noncrossmatch method were tested by an ISCX. ABO test results were concordant for 7115 of 7124 patient samples and discordant for nine. Seven of the nine discordant patient test results were resolved prior to transfusion, and two were inadvertently overlooked. ABO test results were concordant for 26 922 of 26 942 donor units and discordant for 20. Seventeen of the 20 discordant donor test results were resolved prior to transfusion and three were inadvertently overlooked. Two ABO incompatibilities were missed by the noncrossmatch method but were detected by the ISCX. Unless clerical errors can be totally eliminated, it may be safer to retain the ISCX (*Arch Pathol Lab Med*. 1989;113:270-272).

Correspondence and Brief Communications

Esophageal Perforation

To the Editor.—We found the article by Yeo and colleagues[1] in the August ARCHIVES to be extremely interesting. Esophageal perforation is a catastrophic event and requires emergent surgical therapy.[2] When the underlying cause is a malignant esophageal obstruction, the prognosis is poor, and the authors are to be commended for their exemplary results.

When confronted with a promptly recognized perforation in a patient with esophageal carcinoma, if the patient is a good operable candidate and the lesion is otherwise believed to be resectable, we agree that resection of the entire thoracic esophagus, including the perforation and tumor, with an immediate esophagogastrostomy may be far safer and more satisfactory than relying on repair and drainage.[2] Unfortunately, these patients usually suffer from multiple difficulties, including substantial nutritional problems and recurrent aspiration pneumonia. The surgeon is then required to undertake a major procedure in a debilitated patient without benefit of optimal preoperative preparation, resulting in a 25% to 30% operative mortality and 50% operative morbidity.[3] Resection and initial diversion may decrease the morbidity but still necessitate subsequent major surgery for reconstruction of the gastrointestinal tract.

Based on our previous results with 18 patients who have undergone surgical placement of an endoesophageal prosthesis for unresectable malignant esophageal carcinoma, with 8 of these patients having an esophagorespiratory fistula, we feel the insertion of an endoesophageal prosthesis is the simplest and most expeditious technique to palliate these extremely sick patients.[4] The introduction of an endoesophageal prosthesis prevents further extravasation and contamination of the mediastinum and thoracic cavity, and drainage manages the previous contamination. These patients, who have an extremely short survival with a dismal quality of life, are then able to be discharged shortly afte procedure, and almost uniformly to ate a regular diet up until their dea We believe that even in the preser of an esophageal malignant perfor tion, the introduction of an endoeso phageal prosthesis offers the best chance for reestablishing an esophageal lumen with minimal morbidity and mortality, and excellent palliation.

CEFOTAN® IM/IV

(cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

r Intravenous or Intramuscular Use
IEF SUMMARY

ICATIONS AND USAGE
ATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the owing infections when caused by susceptible strains of the designated organisms:
nary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus tabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia tgeri,* and *Morganella morganii*).
wer respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *phylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* cluding ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli.*
in and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicil-ase-producing strains), *Staphylococcus epidermidis,* Streptococcus pyogenes* and *Streptococcus* ecies (excluding enterococci), and *E coli.*
ecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicil-se-producing strains), *Staphylococcus epidermidis,* Streptococcus* species (excluding entero-ci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, tus, B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *coccus* and *Peptostreptococcus* species†).
bdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae*†), *Strepto-s* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, taiotaomicron*).
e and joint infections caused by *Staphylococcus aureus.*†
OTE: Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.
fficacy for this organism in this organ system was studied in fewer than ten infections.
OPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain stoperative infections in patients undergoing surgical procedures that are classified as clean ntaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, nsurethral surgery, biliary tract surgery, and gastrointestinal surgery).
The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In tients undergoing cesarean section, CEFOTAN should be administered intravenously after the mping of the umbilical cord.
f there are signs and symptoms of infection, specimens for culture should be obtained for ntification of the causative organism so that appropriate therapeutic measures may be initiated.
NTRAINDICATIONS
FOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.
RNINGS
fore therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the tient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, nicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. tibiotics should be administered with caution to any patient who has demonstrated some form of ergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. rious acute hypersensitivity reactions may require epinephrine and other emergency measures. Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-ectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop rrhea in association with antibiotic use.
Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit over-owth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of tibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro. Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be naged with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not re-ved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for anti-otic-associated pseudomembranous colitis produced by *C difficile.* Other causes should also be considered.
ECAUTIONS
NERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in over-owth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection es occur during therapy, appropriate measures should be taken.
In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in othrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutri-nal state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K ministered as indicated.
CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, rticularly colitis.
FORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction aracterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine,) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the gestion of alcoholic beverages following the administration of CEFOTAN.
UG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if erapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibi-ics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible at nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
RUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur th Benedict's or Fehling's solution.
As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of rum and urine creatinine levels of Jaffe reaction and produce false increases in the levels atinine reported.
RCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in imals have not been performed to evaluate carcinogenic potential, no mutagenic potential of fotetan was found in standard laboratory tests.
Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 0 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be

CEFOTAN® (cefotetan disodium)

developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.
USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.
PEDIATRIC USE: Safety and effectiveness in children have not been established.
ADVERSE REACTIONS
In clinical studies the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).
DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.
IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.
HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.
1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21).
